# Chapter 1

## Theoretical Framework

- Introduce sm
- brief history
- current areas of study
- Reference relevance to rest of thesis (studying hbb)

The Standard Model (SM) of particle physics is the theory describing all known elementary particles and their interactions via three of the four fundamental forces. Developed by merging the successful theories of classical quantum mechanics and relativity in the second half of the 20th century, the SM's position today at the centre of our understanding of the nature of the universe is firmly established by an unparalleled level of agreement between the predictions from the model and experimental results [1,2].

The SM has predicted the discovery of the top and bottom quarks [3–5], the  $W$  and  $Z$  bosons [6], and the tau neutrino [7]. The last missing piece of the SM to be discovered was the Higgs boson, first posited in **X**. After its discovery in 2012 **citation**, much work has been ongoing on carrying out detailed measurements of its mass and interactions with other particles.

This thesis looks at understanding Higgs decays...

## 1.1 The Standard Model

The SM is formulated in the language of Quantum Field Theory (QFT). In this framework, particles are localised excitations of corresponding quantum fields, which are operator-valued distribution across spacetime.

Central to QFT is the Lagrangian density which describes the kinematics and dynamics of a field. Observations of conserved quantities are linked, via Noether's theorem, to symmetries which are expressed by the Lagrangian. Alongside Global Poincaré symmetry, the SM Lagrangian observes a local non-Abelian  $SU(3)_C \otimes SU(2)_L \otimes U(1)_Y$  gauge symmetry. Gauge symmetries leave observable properties of the system unchanged when certain gauge transformations are applied to the fields. The full Lagrangian of the SM can be broken up into distinct terms corresponding to the different sectors.

$$\mathcal{L}_{\text{SM}} = \mathcal{L}_{\text{EW}} + \mathcal{L}_{\text{QCD}} + \mathcal{L}_{\text{Higgs}} + \mathcal{L}_{\text{Yukawa}} \quad (1.1)$$

The SM provides a mathematical description of how the four fundamental forces interact with the matter content of the universe. The SM contains 12 spin-1/2 fermions, listed in table 1.1, and 5 bosons listed in table 1.2.

Generation	Leptons			Quarks		
	Flavour	Mass [MeV]	Charge [ $e$ ]	Flavour	Mass [MeV]	Charge [ $e$ ]
First	$e$	0.511	-1	$u$	2.16	$2/3$
	$\nu_e$	$< 1.1 \times 10^{-6}$	0	$d$	4.67	$-1/3$
Second	$\mu$	105.7	-1	$c$	$1.27 \times 10^3$	$2/3$
	$\nu_\mu$	$< 0.19$	0	$s$	93.4	$-1/3$
Third	$\tau$	1776.9	-1	$t$	$173 \times 10^3$	$2/3$
	$\nu_\tau$	$< 18.2$	0	$b$	$4.18 \times 10^3$	$-1/3$

**Table 1.1:** The half-integer spin fermions of the SM [8]. Three generations of particles are present. Also present (unlisted) are the antiparticles, which are identical to the particles up to a reversed charge sign.

Name	Symbol	Mass [GeV]	Charge [e]	Spin
Photon	$\gamma$	$< 1 \times 10^{-27}$	$< 1 \times 10^{-46}$	1
Weak boson	$W^\pm$	$80.377 \pm 0.012$	$\pm 1$	1
Weak boson	$Z$	$91.1876 \pm 0.0021$	0	1
Gluon	$g$	0	0.5	1
Higgs	$H$	$125.25 \pm 0.17$	0	0

**Table 1.2:** The integer spin bosons of the SM [8]. The photon, weak bosons and gluons are gauge bosons arising from gauge symmetries, and carry the four fundamental forces of the SM.

### 28 1.1.1 Quantum Electrodynamics

Consider a Dirac spinor field  $\psi = \psi(x)$  and its adjoint  $\bar{\psi} = \psi^\dagger \gamma^0$ , where  $\psi^\dagger$  denotes the Hermitian conjugate of  $\psi$ . The field  $\psi$  describes fermionic spin-1/2 particle, for example an electron. The Dirac Lagrangian density is

$$\mathcal{L}_{\text{Dirac}} = \bar{\psi}(i\cancel{\partial} - m)\psi, \quad (1.2)$$

where  $\cancel{\partial} = \gamma^\mu \partial_\mu$  denotes the contraction with the Dirac gamma matrices  $\gamma^\mu$  (summation over up-down pairs of indices is assumed). Application of the Euler-Lagrange equation on eq. (1.2) yields the Dirac equation

$$(i\cancel{\partial} - m)\psi = 0. \quad (1.3)$$

Suppose some fundamental symmetry that requires invariance under a  $U(1)$  local gauge transformation

$$\psi \rightarrow \psi' = \psi e^{-iq\alpha(x)}, \quad (1.4)$$

where  $\alpha$  varies over every spacetime point  $x$ . Under this transformation, the Dirac equation transforms as

$$(i\cancel{\partial} - m)\psi e^{-iq\alpha(x)} + q\cancel{\partial}\alpha(x)\psi e^{-iq\alpha(x)} = 0. \quad (1.5)$$

For the Dirac equation to remain invariant under the transformation in eq. (1.4), a new field  $A_\mu$  which transforms as  $A_\mu \rightarrow A'_\mu = A_\mu + \partial_\mu \alpha(x)$  must be added. The

mention  
EoMs?

transformed interaction term

$$-q\cancel{A}\psi \rightarrow -q\cancel{A}\psi e^{-iq\alpha(x)} - q\cancel{\partial}\alpha(x)\psi e^{-iq\alpha(x)} \quad (1.6)$$

will then cancel the asymmetric term in eq. (1.5) as required. The  $U(1)$  invariant Lagrangian can therefore be constructed by adding an interaction between  $\psi$  and  $A_\mu$  to eq. (1.2). The kinetic term for the new field  $A_\mu$  is also added in terms of  $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ , which is trivially invariant under the transformation in eq. (1.4). The interaction term is absorbed into the covariant derivative  $D_\mu = \partial_\mu + iqA_\mu$ , thus named as it transforms in the same way as the field  $\psi$ . This yields the QED Lagrangian

$$\mathcal{L}_{\text{QED}} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \bar{\psi}(i\not{D} - m)\psi, \quad (1.7)$$

29 A quadratic term  $A_\mu A^\mu$  is not invariant and therefore the the field  $A_\mu$  must be  
 30 massless. Requiring invariance under local  $U(1)$  gauge transformations necessitated  
 31 the addition of a new field  $A_\mu$ , corresponding to photons, which interact with charged  
 32 matter.

improve in-  
terpretation

### 33 1.1.2 Quantum Chromodynamics

Quantum Chromodynamics (QCD) is the study of quarks, gluons and their interactions. Quarks and gluons carry colour charge, which comes in three kinds, called red, green and blue. While the  $U(1)$  symmetry group in section 1.1.1 was Abelian, the QCD Lagrangian is specified by requiring invariance under transformations from the non-Abelian  $SU(3)$  group, making it a Yang-Mills theory [9] which requires the addition of self-interacting gauge fields. The infinitesimal  $SU(3)$  group generators are given by  $T_a = \lambda_a/2$ , where  $\lambda_a$  are the eight Gell-Mann matrices. These span the space of infinitesimal group transformations and do not commute with each other, instead satisfying the commutation relation

$$[T_a, T_b] = if_{abc}T_c, \quad (1.8)$$

where  $f_{abc}$  are the group's structure constants. Consider the six quark fields  $q_k = q_k(x)$ . Each flavour of quark  $q_k$  transforms in the fundamental triplet representa-

tion, where each component of the triplet corresponds to a different value of the colour quantum number.  $G_{\mu\nu}^a$  are the eight gluon field strength tensors, one for each generator  $T_a$ , defined as

$$G_{\mu\nu}^a = \partial_\mu A_\nu - \partial_\nu A_\mu - g_s f^{abc} A_\mu^b A_\nu^c, \quad (1.9)$$

where  $A_\mu^a$  are the gluon fields and  $g_s$  is the strong coupling constant. The covariant derivative is written as

$$D_\mu = \partial_\mu + ig_s T_a A_\mu^a. \quad (1.10)$$

The full QCD Lagrangian is then given by

$$\mathcal{L}_{\text{QCD}} = -\frac{1}{4} G_{\mu\nu}^a G_a^{\mu\nu} + q_k (i \not{D} - m_k) q_k. \quad (1.11)$$

34 Cubic and quartic terms of the gauge fields  $A_\mu^a$  appear in the Lagrangian, leading  
35 to the gluon's self interaction.

36 The QCD coupling constant  $g_s$  varies, or “runs”, with energy. At lower energy  
37 scales (and corresponding larger distance scales) the interaction is strong. This  
38 leads to quark confinement, whereby an attempt to isolate individual colour-charged  
39 quarks requires so much energy that additional quark-antiquark are produced. At  
40 higher energy scales (and corresponding smaller distance scales), asymptotic freedom  
41 occurs as the interactions become weaker, allowing perturbative calculations to be  
42 performed. Hadrons are bound states of quarks. They are invariant under  $SU(3)$   
43 gauge transformations (i.e. are colour-charge neutral, or colourless).

### 44 1.1.3 The Electroweak Sector

45 The weak and electromagnetic forces are unified in the Glashow-Weinberg-Salam  
46 (GWS) model of electroweak interaction [10–12]. The Lagrangian is specified by  
47 requiring invariance under the symmetry group  $SU(2)_L \otimes U(1)_Y$ , as motivated by a  
48 large amount of experimental data. Here,  $SU(2)_L$  is referred to as weak isospin and  
49  $U(1)_Y$  as weak hypercharge. (the product of the isospin and hypercharge groups.).

The generators of  $SU(2)_L$  are  $T_a = \sigma_a/2$ , where  $\sigma_a$  are the three Pauli spin matrices which satisfy the commutation relation

$$[T_a, T_b] = i\varepsilon_{abc}T_c. \quad (1.12)$$

50 The generator of  $U(1)_Y$  is  $Y = 1/2$ . Each generator corresponds to an gauge field,  
 51 which, after symmetry breaking (discussed in section 1.2.1), give rise to the massive  
 52 vector bosons,  $W^\pm$  and  $Z$ , and the massless photon. The massive vector bosons are  
 53 the carriers of the weak force.

54 The weak force violates parity conservation [13–15], i.e. invariance under parity  
 55 transformations (mirror reflections). Only left handed fermions participate in the  
 56 weak interaction. There are no right handed neutrinos in the standard model. The  
 57 Standard Model incorporates parity violation by expressing the weak interaction as  
 58 a chiral gauge interaction. Only the left-handed components of particles and right-  
 59 handed components of antiparticles participate in weak interactions in the Standard  
 60 Model. The weak force couples only to left handed particles in currents of the form  
 61  $J^\mu = \bar{\nu}_e \gamma^\mu (1 - \gamma^5) e$  or  $J^\mu = \bar{u} \gamma^\mu (1 - \gamma^5) \tilde{d}$ . The  $\tilde{d}$  state is due to the quark mixing:  
 62 mass eigenstates are not the same as weak eigenstates.

63 Furthermore, CP violation has been observed from the weak sector. CP violation is  
 64 one of the three necessary Sakharov conditions required to produce baryon asymme-  
 65 try in the universe. Since the SM alone does not appear to have enough CP violation  
 66 to generate the cosmologically observed matter-antimatter asymmetry, looking for  
 67 signs of more experimental CP violation is considered to be a promising way to  
 68 discover new physics.

## 69 1.2 The Higgs Mechanism

70 Experimentally it was known that the weak forces contains a charged current and  
 71 had a weak effective strength, suggestive of a massive mediating gauge particle.  
 72 However, directly adding mass to the gauge bosons in a non-Abelian theory breaks  
 73 the symmetry. Instead, the gauge bosons can gain mass through interaction with  
 74 a scalar Higgs field, known as the Brout–Englert–Higgs mechanism [16–18]. An  
 75 overview is given below. Spontaneous symmetry breaking (SSB) is the transition of

**Figure 1.1:** The Higgs potential  $V(\phi)$  of the complex scalar field  $\phi$ , with a choice of  $\mu^2 < 0$  leading to a continuous degeneracy in the vacuum states.

76 a physical system from a state of manifest symmetry to a state of hidden, or “broken”,  
 77 symmetry. In particular, this applies to physical systems where the Lagrangian  
 78 observes some symmetry, but the lowest energy vacuum states do not exhibit that  
 79 same symmetry. The symmetry is broken for perturbations around the vacuum  
 80 state.

Consider an  $SU(2)$  gauge field coupled with a complex scalar field  $\phi$ , which trans-  
 forms as an  $SU(2)$  spinor (a weak isospin doublet). Omitting the kinetic term of  
 the gauge fields, and writing  $\phi^2 \equiv \phi^\dagger \phi$ , the Lagrangian is

cite weak  
gauge fields,  
non-Abelian  
local

$$\mathcal{L} = (D_\mu \phi)^\dagger (D^\mu \phi) - [\mu^2 \phi^2 + \lambda \phi^4], \quad (1.13)$$

where the covariant derivative is given by

$$D_\mu = \partial_\mu + ig A_\mu^a T^a, \quad (1.14)$$

81 and  $T^a$  are the generators of  $SU(2)$ . The potential term  $V(\phi)$  is made up of a  
 82 quadratic and quartic term in the scalar field  $\phi$ , which contain an arbitrary parame-  
 83 ter, respectively  $\lambda$  and  $\mu$ . The quartic term gives the field self-interaction be negative  
 84 as the potential must be bounded from below. The quadratic term can be positive  
 85 or negative. In the case where the quadratic term is positive, it is interpreted as a  
 86 mass term for the scalar field By choosing  $\mu^2 < 0$  the field becomes unphysical due  
 87 to its negative mass.

In order to obtain a physical interpretation of the Lagrangian in eq. (1.13), expand around the vacuum state. The vacuum expectation value (VEV) is expected value of the field  $\phi$  which minimises the potential  $V(\phi)$  (equivalently the expected value of the field operator  $\phi$  when the system is in a vacuum state,  $\langle\phi\rangle_0 \equiv \langle 0|\phi|0\rangle \equiv \phi_0$ ). Minimising the potential yields

$$\phi_0^2 = -\mu^2/\lambda = v^2. \quad (1.15)$$

Due to the shape of the potential in fig. 1.1, there is degeneracy in the direction that the complex doublet  $\phi$  points. As all the different VEVs with this norm minimise the potential and therefore yield identical physics, we can arbitrarily choose one to base calculation on. Choosing, then, the VEV to lie along the  $n$ -th direction of the field, and adding the fluctuations back in yields VEV is taken along a single direction to preserve one generator - the  $U(1)$  symmetry of QED. Now expand the Lagrangian around one component of the field  $\phi_0 = v + \sigma$ , and take  $\phi_i = \pi_i$ ,  $i = 1, 2, 3$ . Written in terms of  $\sigma$  and  $\pi_i$ , the Lagrangian becomes The Lagrangian is expanded around one of these minima as  $\phi = v + \sigma$ , with  $\sigma = \frac{1}{\sqrt{2}}(\xi + i\chi)$ .

$$\phi = \begin{pmatrix} \phi_{RE} \\ f + v \end{pmatrix} \quad (1.16)$$

88 The resulting Lagrangian, neglecting interaction terms which do not play a role in  
89 the Higgs mechanism, is

90 move to the unitary gauge

91 Different vacuum states are traversed by moving in flat directions of the potential.  
92 Particles corresponding to fluctuations of the field along the flat directions in the  
93 potential are massless as they don't cost energy to attain.

94 Goldstone stuff,  $\dim G - H$ , residual symmetry, unbroken generators, The Goldstone  
95 theorem was discussed in the context *global symmetries*, in which the Lagrangian is  
96 invariant under a transformation that is independent of the choice of spacetime point.  
97 However, the results derived are not the same for *gauge* symmetry transformations.  
98 In this case, Goldstone bosons are absorbed by the theory and give mass to the

99 massless gauge bosons associated with each broken generator. This is the *Higgs*  
 100 *mechanism*, and is way the vector bosons, and other particles, acquire mass.

101 Massive gauge bosons are unique to the weak sector. As a consequence of massive  
 102 bosons, the weak force has a short range, and so it appears weak even though its  
 103 intrinsic strength is comparable to that of QED.

### 104 1.2.1 Electroweak Symmetry Breaking

105 The  $SU(3)_C \otimes SU(2)_L \otimes U(1)_Y$  is spontaneously broken to  $SU(3)_C \otimes U(1)_\gamma$ .

106 the three  $A_\mu^a$  from  $SU(2)_L$  and  $B_\mu$  from  $U(1)_Y$ . After symmetry breaking

107 Spontaneous symmetry breaking (SSB) occurs when a system moves from a sym-  
 108 metrical to an unsymmetrical state. In the context of QFT, symmetry means the  
 109 Lagrangian of a system is invariant under a transformation. These symmetry prop-  
 110 erties are required for the theory to be renormalizable. SSB occurs when the La-  
 111 grangian for the lowest energy vacuum solution does not exhibit the same symmetry  
 112 as the excited states. For a field to be able to have the standard particle interpre-  
 113 tation, it must be linear in creation and annihilation operators. Such a field has a  
 114 vanishing vacuum expectation value. As such, fields with nonvanishing VEV cannot  
 115 correspond to particles. This is the motivation behind the field substitution in equa-  
 116 tion (4.3), where the newly introduced field has a vanishing VEV by construction.  
 117 Note that the original field remains massless, whereas the newly introduced field  
 118 (corresponding to a physical particle) gains mass.

119 The Goldstone theorem was discussed in the context global symmetries, in which the  
 120 Lagrangian is invariant under a transformation that is independent of the choice of  
 121 spacetime point. However, the results derived are not the same for gauge symmetry  
 122 transformations. In this case, Goldstone bosons are absorbed by the theory and  
 123 give mass to the massless gauge bosons associated with each broken generator. This  
 124 is the Higgs mechanism, and is way the vector bosons, and other particles, acquire  
 125 mass.

## Chapter 2

# The Large Hadron Collider and the ATLAS Detector

## 2.1 Overview

The Large Hadron Collider (LHC) at CERN has extended the frontiers of particle physics through its unprecedented energy and luminosity. In 2010, the LHC collided proton bunches, each containing more than  $10^{11}$  particles, 20 million times per second, providing 7 TeV proton-proton collisions at instantaneous luminosities of up to  $2.1 \times 10^{32} \text{ cm}^{-2} \text{ s}^{-1}$ .

### 2.1.1 The ATLAS Detector

The ATLAS detector at the LHC covers nearly the entire solid angle around the collision point.<sup>1</sup> It consists of an inner tracking detector surrounded by a thin superconducting solenoid, electromagnetic and hadron calorimeters, and a muon spectrometer incorporating three large superconducting air-core toroidal magnets.

---

<sup>1</sup>ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point in the centre of the detector and the  $z$ -axis along the beam pipe. The  $x$ -axis points from the interaction point to the centre of the LHC ring, and the  $y$ -axis points upwards. Cylindrical coordinates  $(r, \phi)$  are used in the transverse plane,  $\phi$  being the azimuthal angle around the  $z$ -axis. The pseudorapidity is defined in terms of the polar angle  $\theta$  as  $\eta = -\ln \tan(\theta/2)$ . Angular distance is measured in units of  $\Delta R \equiv \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$ .

145 The inner-detector system (ID) is immersed in a 2 T axial magnetic field and pro-  
 146 vides charged-particle tracking in the range  $|\eta| < 2.5$ . The high-granularity silicon  
 147 pixel detector covers the vertex region and typically provides four measurements per  
 148 track, the first hit normally being in the insertable B-layer (IBL) installed before  
 149 Run 2 [19,20]. It is followed by the silicon microstrip tracker (SCT), which usually  
 150 provides eight measurements per track. These silicon detectors are complemented by  
 151 the transition radiation tracker (TRT), which enables radially extended track recon-  
 152 struction up to  $|\eta| = 2.0$ . The TRT also provides electron identification information  
 153 based on the fraction of hits (typically 30 in total) above a higher energy-deposit  
 154 threshold corresponding to transition radiation. Reconstructed charged particles are  
 155 assumed to have a charge of  $\pm 1$ .

156 A complete overview of the ATLAS detector is provided in Ref. [21].

## 157 2.2 Old Detector Notes

158 High level information taken from [21]. Initial (circa 2000) information about each  
 159 sub-detector system is available in the respective technical design reports (TDRs).  
 160 Note that much of the specifics will therefore be outdated.

161 The detector is made up of several specialised subdetectors. In order of increasing  
 radial distance from the point of particle interaction, these are:

**Figure 2.1:** The Inner Detector (ID). After run 3, the ID will be replaced by the ITk.

162

**Figure 2.2:** Updated ID, showing the IBL.

- 163 1. **Inner detector (ID).** High resolution tracking (coverage over  $|\eta| < 2.5$ ) hard-  
 164 ware, contained in a superconducting solenoidal magnet with a central field of  
 165 2T. Combination of the two systems below yields robust pattern recognition  
 166 and high precision in both  $\phi$  and  $z$  coordinates.

Tracking is useful for: impact parameter measurements, vertexing for heavy-flavour and  $\tau$  tagging. Momentum resolution is sufficient to identify the charge sign of particles up to the highest energies expected at LHC. After run 3, the ID will be replaced by the ITk.

a) **Pixel Detectors.** Arranged in three cylindrical barrels at increasing radio ( 4, 11, 14 cm), and four discs on each side. Radiation hardened readout electronics. Full angular coverage. 140 million readout channels. The specification determines the impact parameter resolution and the ability of the ID to find short-lived particles such as b-quarks and  $\tau$ -leptons. Silicon pixels. The pixel detector dominates measurements of track impact parameters and provides vertex reconstruction capabilities. Table 2.2 summarises the main features of the pixel subsystem. Each pixel module is required to have a high granularity (resolution) to maintain a low occupancy (high sparsity to resolve different tracks). The pixel layers consist of the three original barrels and three disks (end-caps), and a new IBL. In order of increasing radius from the beam-line the pixel detector consists of the following layers

i. **Insertable B-Layer (IBL).** The innermost layer of pixel detectors, 3.3cm from beam axis. Added in 2014. It was built to cope with high radiation and occupancy, and is the first large scale application of 3D sensors and CMOS 130nm technology.

ii. Three barrel layers: Layer 0 (also sometime called the b-layer or B-layer), Layer 1 and Layer 2. Additionally there two identical endcap regions, each with three disk layers.

b) **Semi-Conductor Tracker (SCT).** Silicon microstrip detectors. Contributes to the measurement of momentum, impact parameter and vertex position. 61 m<sup>2</sup> of silicon detector, 6.2 million readout channels.

c) **Transition Radiation Tracker (TRT).** Continuous tracking using straw detectors. The straws run parallel to the  $z$  axis and therefore the TRT only provides  $R$ - $\phi$  information. Radial straws on the endcaps. Electron identification capability is added by employing xenon gas to detect transition-radiation photons created in a radiator between the straws. A good pattern recognition performance is assured by the continuous tracking. Within the radial space available, the straw spacing has been optimised for tracking at

the expense of electron identification, which would be improved by a greater path length through the radiator material and fewer active straws. The TRT contributes to the accuracy of the momentum measurement in the ID. It aids the pattern recognition by the addition of around 36 hits per track, and allows a simple and fast L2 track trigger to be implemented. It allows the ID to reconstruct  $V_0$ s which are especially interesting in CP-violating  $B$  decays. In addition it provides additional discrimination between electrons and hadrons.

**Figure 2.3:** The ECal (orange) and HCal (grey, dark orange)

2. **Calorimeters** measure the energy of particle passing through them. They cover  $|\eta| < 4.9$  using a range of different techniques depending on the location in  $\eta$ . Over the  $\eta$  region matched to the inner detector, the fine granularity of the EM calorimeter is ideally suited for precision measurements of electrons and photons. The coarser granularity of the rest of the calorimeter is sufficient to satisfy the physics requirements for jet reconstruction and  $E_T^{\text{miss}}$  measurements. Particles entering the calorimeter, will cause a particle shower inside the calorimeter. Calorimeters must provide good containment for electromagnetic and hadronic showers, and must also limit punch-through (leakage of non muon particles) into the muon system (dependent on the radial depth of the calorimeter system). The calorimeters measure the energies and positions of electrons, photons and jets. In doing so they stop these particles penetrating into the muon spectrometer. When a relativistic photon or electron is incident on a thick absorber, it initiates an electromagnetic cascade, generating secondary photons by bremsstrahlung ( $e \rightarrow e\gamma$ ) and electrons by pair production ( $\gamma \rightarrow e^+e^-$ ).

A narrow transverse profile is characteristic of an electromagnetic cascade. Hadrons passing through matter also initiate cascades through inelastic hadron-nuclei interactions. The shower produces secondary hadrons and leptons and has a comparatively wide transverse profile. The nuclear interaction length is about an order of magnitude greater than the radiation length of the material. Therefore, like most general purpose experiments, ATLAS uses two different

calorimetry systems to measure electrons and photons (the ECal) and hadrons (the HCal).

a) **Liquid Argon (LAr) Electromagnetic (EM) Calorimeter (Ecal).**

The EM calorimeter is divided into a barrel part ( $|\eta| < 1.475$ ) and two end-cap components ( $1.375 < |\eta| < 3.2$ ), each housed in their own cryostat. The EM calorimeter is a lead-LAr detector with accordion-shaped kapton electrodes and lead absorber plates over its full coverage. The accordion geometry provides complete  $\phi$  symmetry without azimuthal cracks. Showers initiated in the lead produce secondary particles which ionise the liquid argon. The charge is collected on copper electrodes and read out. Additionally, multiple samplings of the shower are used to resolve its pointing vector.

b) **Hadronic calorimeters (HCal).**

- The tile calorimeter is placed directly outside the EM calorimeter envelope. Its barrel covers the region  $|\eta| < 1.0$ , and its two extended barrels (larger  $z$  displacement) the range  $0.8 < |\eta| < 1.7$ . It is a sampling calorimeter using steel as the absorber and scintillating tiles as the active material. The HCal barrel uses iron absorbers to initiate hadronic cascades and plastic scintillator tiles as the active
- LAr hadronic end-cap calorimeter (HEC). Located directly behind (in  $z$ ) the end-cap electromagnetic calorimeter and sharing the same LAr cryostats. The high level of radiation in the forward regions would cause severe damage to plastic scintillators. In the end-caps, parallel copper plates are submerged in liquid argon, which is preferred as the active medium because of its inherent radiation hardness.
- LAr forward calorimeter (FCal).

**Figure 2.4:** The muon detectors

3. **Muon system.** Based on the magnetic deflection of muon tracks in the large superconducting air-core toroid magnets, instrumented with separate trigger and high-precision tracking chambers. This magnet configuration provides a

field which is mostly orthogonal to the muon trajectories, while minimising the degradation of resolution due to multiple scattering. In the barrel region, tracks are measured in chambers arranged in three cylindrical layers around the beam axis; in the transition and end-cap regions, the chambers are installed in planes perpendicular to the beam, also in three layers.

## 2.3 Trigger system

An LHCb trigger table borrowed from `hepthesis` is shown in Table 2.1:

**Table 2.1:** Characteristics of the trigger levels and offline analysis.

	L0	L1	HLT
Input rate	40 MHz	1 MHz	40 kHz
Output rate	1 MHz	40 kHz	2 kHz
Location	On detector	Counting room	Counting room

## 2.4 Reconstructed Physics Objects

### 2.4.1 Tracks

The trajectories of charged particles are reconstructed as tracks from the energy depositions (hits) of the particles as they traverse the sensitive elements of the inner detector. Track selection follows the loose selection described in Ref. [22] and outlined in table 2.2, which was found to improve the flavour tagging performance compared to previous tighter selections, whilst ensuring good resolution of tracks and a low fake rate [23]. The transverse IP  $d_0$  and longitudinal IP  $z_0$  are measured with respect to the hard scatter primary vertex, defined as the reconstructed primary vertex (PV) with the largest sum of the transverse momentum ( $p_T$ ) of the associated tracks squared,  $\sum p_T^2$ .

**Table 2.2:** Quality selections applied to tracks, where  $d_0$  is the transverse IP of the track,  $z_0$  is the longitudinal IP with respect to the PV and  $\theta$  is the track polar angle. Shared hits are hits used on multiple tracks which have not been classified as split by the cluster-splitting neural networks [23]. Shared hits on pixel layers are given a weight of 1, while shared hits in the SCT are given a weight of 0.5. A hole is a missing hit, where one is expected, on a layer between two other hits on a track.

Parameter	Selection
$p_T$	$> 500 \text{ MeV}$
$ d_0 $	$< 3.5 \text{ mm}$
$ z_0 \sin \theta $	$< 5 \text{ mm}$
Silicon hits	$\geq 8$
Shared silicon hits	$< 2$
Silicon holes	$< 3$
Pixel holes	$< 2$

## 2.4.2 Old stuff

### Triggers and Data Acquisition (TDAQ)

The trigger system has three distinct levels: L1, L2, and the event filter. Each trigger level refines the decisions made at the previous level and, where necessary, applies additional selection criteria. The data acquisition system receives and buffers the event data from the detector-specific readout electronics, at the L1 trigger accept rate. The first level uses a limited amount of the total detector information to make a decision in in a short time.

### The Trigger System

The L1 trigger searches for high transverse-momentum muons, electrons, photons, jets, and  $\tau$ -leptons decaying into hadrons, as well as large missing and total transverse energy. Its selection is based on information from a subset of detectors. High transverse-momentum muons are identified using trigger chambers in the barrel and end-cap regions of the spectrometer. Calorimeter selections are based on reduced-granularity information from all the calorimeters. Results from the L1 muon and calorimeter triggers are processed by the central trigger processor, which implements

combinations of different trigger selections. In each event, the L1 trigger also defines one or more Regions-of-Interest (RoI's), i.e. the geographical coordinates in  $\eta$  and  $\phi$ , of those regions within the detector where its selection process has identified interesting features. The RoI data include information on the type of feature identified and the criteria passed, e.g. a threshold. This information is subsequently used by the high-level trigger.

The L2 selection is seeded by the RoI information provided by the L1 trigger. L2 selections use, at full granularity and precision, all the available detector data within the RoI's (approximately 2% of the total event data). The L2 menus are designed to reduce the trigger rate to approximately 3.5 kHz, with an event processing time of about 40 ms, averaged over all events. The final stage of the event selection is carried out by the event filter, which reduces the event rate to roughly 200 Hz. Its selections are implemented using offline analysis procedures within an average event processing time of the order of four seconds.

### 2.4.3 Jets

Jets are reconstructed from particle-flow objects [24] using the anti- $k_T$  algorithm [25] with a radius parameter of 0.4. The jet energy scale is calibrated according to Ref. [26]. Jets are also required not to overlap with a generator-level electron or muon from  $W$  boson decays. All jets are required to have a pseudorapidity  $|\eta| < 2.5$  and  $p_T > 20$  GeV. Additionally, a standard selection using the Jet Vertex Tagger (JVT) algorithm at the tight working point is applied to jets with  $p_T < 60$  GeV and  $|\eta| < 2.4$  in order to suppress pileup contamination [27]. Tracks are associated to jets using a  $\Delta R$  association cone, the width of which decreases as a function of jet  $p_T$ , with a maximum cone size of  $\Delta R \approx 0.45$  for jets with  $p_T = 20$  GeV and minimum cone size of  $\Delta R \approx 0.25$  for jets with  $p_T > 200$  GeV. If a track is within the association cones of more than one jet, it is assigned to the jet which has a smaller  $\Delta R(\text{track}, \text{jet})$ .

Jet flavour labels are assigned according to the presence of a truth hadron within  $\Delta R(\text{hadron}, \text{jet}) < 0.3$  of the jet axis. If a  $b$ -hadron is found the jet is labelled a  $b$ -jet. In the absence of a  $b$ -hadron, if a  $c$ -hadron is found the jet is called a  $c$ -jet. If no  $b$ - or  $c$ -hadrons are found, but a  $\tau$  is found in the jet, it is labelled as a  $\tau$ -jet, else it is labelled as a light-jet.

## 3.1 *b*-hadron Reconstruction

### 3.1.1 *b*-hadron Decay Topology

*b*-hadrons are quasi-stable bound states of quarks, where one of the quarks is a bottom quark (*b* quark). The proper lifetimes  $\tau$  of the various *b*-hadrons are similar and relatively long, with  $\tau \sim 10^{-12}$  s. This lifetime corresponds to a proper decay length  $c\tau \sim 300 \mu\text{m}$ . In the rest frame of the detector, the typical *b*-hadron travels a distance  $d = \beta\gamma c\tau$  before decaying, where at high energies  $\gamma \sim E_B/m_B$ . For a 1 TeV *b*-hadron, this gives  $d \sim 60$  mm - well beyond the radius of the first pixel layer (IBL) at 33 mm. At the LHC, *b* quarks are generated in the hard scattering of proton-proton (*pp*) collisions. They quickly hadronize into a *b*-hadron, which is often initially in an excited state due to the high energies of the *pp* collisions at the LHC ( $\sqrt{s} = 13$  TeV). The hadronisation process is hard - around 70-80% of the *b* quark's momentum goes into the *b*-hadron, with the rest being radiated as other particles. The excited *b*-hadron will quickly fragment (i.e. de-excite) by radiating particles, which are prompt (they are formed closed to the primary vertex). These fragmentation particles have an increasing multiplicity and collimation to the *b*-hadron axis as the  $p_T$  of the *b*-hadron increases. The de-excited *b*-hadron

subsequently weakly decays to on average 4 or 5 particles (the multiplicity of the decay products of the weak decay of the  $b$ -hadron is unaffected by increases in the  $b$ -hadron  $p_T$ ).

Due to their lifetimes, energetic  $b$ -hadrons can travel a significant distance from the primary  $pp$  interaction point before decaying to a spray of collimated stable particles. This signature is registered in the detector as a displaced jet. Due to the elements of the CKM matrix,  $b$ -hadrons decay with a high probability to D hadrons (which contain a  $c$  quark), which also have significant lifetimes - this can lead to reconstructed tertiary vertices in the jet core. The typical features of a  $b$ -jet, and in particular the large track impact parameter  $d_0$  which can result from displaced decays, are shown in fig. 3.1. Many ATLAS analyses rely on a method of tagging jets instantiated by  $b$  quarks and rejecting jets created from other quarks ( $c$  and light flavours  $u, d, s$ ). These “ $b$ -tagging” algorithms work by discriminating against the unique signatures of  $b$ -jets discussed above.  $b$ -tagging relies on the efficient and accurate reconstruction the tracks corresponding to the  $b$ -hadron decay products. These tracks are then used as inputs to vertex reconstruction algorithms and jet making algorithms.

### 3.1.2 $b$ -hadron Decay Track Reconstruction

A necessary requirement for successful jet  $b$ -tagging is the efficient and accurate reconstruction of the charged particle trajectories in the jet. For high  $p_T$  jets ( $p_T$

**Figure 3.1:** Diagram of a typical  $b$ -jet (blue) which has been produced along with two light jets (grey). The  $b$ -hadron has travelled a significant distance from the primary interaction point (pink dot) before its decay. The large transverse impact parameter  $d_0$  is a characteristic property of the trajectories of  $b$ -hadron decay products.

chapters/3.tracking/figs/high-pt-b-tracks.png

**Figure 3.2:** As  $b$ -hadron  $p_T$  increases, the time of flight of the B increases, so tracks will have less room to diverge before reaching detector elements. To compound the problem, the collimation of the tracks increases. The detector may then be unable to resolve individual tracks.

368 > 200 GeV) this task becomes difficult due to a combination of effects. As the jet  
 369 energy increases, the track multiplicity of the jet increases due to the presence of ad-  
 370 ditional fragmentation tracks. Tracks in the jet also become increasingly collimated  
 371 as their inherited transverse momentum increases. Together, these two effects lead  
 372 to a very high density of charged particles in the jet core, making reconstruction  
 373 difficult. At high energies, the increased decay length of B (and D) hadrons means  
 374 that decay products have less of an opportunity to diverge before reaching the first  
 375 tracking layers of the detector. If the decay takes place very close to a detector  
 376 layer, or if the decays are sufficiently collimated, hits left by nearby particles may  
 377 not be resolved individually, leading to merged clusters (shown in fig. 3.2). Shared  
 378 hits generally predict bad tracks. As such, shared hits are heavily penalised during  
 379 reconstruction (and in particular as part of ambiguity solving). However, in the  
 380 core of high  $p_T$   $b$ -jets, where decay particles are displaced from the primary vertex  
 381 and are highly collimated, the density of particles is high enough that the probab-  
 382 ility of clusters being merged increases dramatically. The presence of merged clusters  
 383 requires that the corresponding tracks share hits (if they are to be reconstructed suc-  
 384 cessfully), which may end up impairing the successfully reconstruction of the track.  
 385 Furthermore, decays may also take place inside the tracking detectors themselves,  
 386 which can lead to missing or wrong innermost cluster assignment. The combination

of effects described above makes reconstructing tracks in the core of high  $p_T$   $b$ -jets particularly challenging.

**Figure 3.3:** Hit multiplicities on the IBL (3.3a) and the pixel layers (3.3b) as a function of the  $p_T$  of the reconstructed track. Tracks from the weak decay of the  $b$ -hadron are shown in red, while fragmentation tracks (which are prompt) are in blue. For each of these, standard tracks and pseudo-tracks are plotted. Hit multiplicities on the pseudo-tracks at high  $p_T$  due to the increased flight of the  $b$ -hadron. The baseline tracks have more hits than the pseudo-tracks, indicating that they are being incorrectly assigned additional hits.

**Figure 3.4:** Track reconstruction efficiency from  $b$ -hadron decay products for baseline ATLAS tracking (black), Bcut+Refit procedures applied (green), pseudo-tracking (blue), and for tracking where the ambiguity solver has been manually removed (orange).

**Figure 3.5:** The total number of pixel hits on tracks from  $b$ -hadron decays as a function of the production radius of the decay product. An excess of hits is assigned to the standard tracks in comparison to the ideal pseudo-tracks.

Concretely, then, the issues relating to high  $p_T$   $b$ -hadron tracking can be factorised into two parts. The first part is a drop in track reconstruction efficiency. As mentioned, tracks originating from high energy  $b$ -hadron decay products can have a high rate of shared hits due to the number of particles present in a high  $p_T$   $b$ -jet and their relative collimation. Additionally, tracks may be missing hits on the inner layers of the detector. This occurs primarily when the decay  $b$ -hadron decays inside the

395 detector. These features of can make it difficult for B decay tracks to meet the  
 396 ambiguity solver's stringent track quality requirements. As a result, many B decay  
 397 tracks are rejected in the ambiguity solving stage, leading to a severe drop in track-  
 398 ing reconstruction efficiency. This is shown by the severe decrease in reconstruction  
 399 efficiency visible when comparing baseline tracking with the ideal pseudo-tracks in  
 400 fig. 3.4. This situation presents a problem: relaxing cuts on shared hits significantly  
 401 degrades the ambiguity solver's power to reject bad tracks. However for  $b$ -hadron de-  
 402 cay tracks it seems these same restrictions on shared hits are seriously impairing the  
 403 reconstruction efficiency of good tracks. The second part of the problem is that, due  
 404 to the high density of clusters available for assignment in the vicinity of the typical  
 405 high energy  $b$ -hadron decay track, and also given the strong positive bias of the am-  
 406 biguity solver towards those tracks with precise pixel measurements (especially the  
 407 innermost IBL measurement), many  $b$ -hadron decay tracks are assigned incorrect in-  
 408 ner layer hits. This is only a problem for those decay products which were produced  
 409 inside the pixel detector as a result of a long-flying  $b$ -hadron, and so do not have a  
 410 correct hit available for assignment (evidenced in fig. 3.8b). The incorrect hits may  
 411 skew the parameters of the track, which can in turn mislead  $b$ -tagging algorithms.  
 412 In particular,  $b$ -tagging algorithms rely heavily on the transverse impact parameter  
 413 significance  $d_0/\sigma(d_0)$  of the track. The quality of this measurement is expected to  
 414 be adversely affected by wrong inner-layer hits on the track. This combination of  
 415 reduced reconstruction efficiency and incorrectly assigned hits is thought to be the  
 416 cause of the observed drop in  $b$ -tagging efficiency at high energies , although it is  
 417 not clear which effect may dominate.

## 418 3.2 Pseudotracks and Ideal Tracks

419 Pseudotracking and ideal tracking are used as benchmarks of the best tracking possi-  
 420 ble given the ATLAS detector. Both pseudotracks and ideal tracks are constructed  
 421 using truth information to group combinations of hits that have been left by the  
 422 same truth particle. As a result, hit-to-track association and track reconstruction  
 423 efficiency are both ideal (given the ATLAS detector). Ideal tracks represent a yet  
 424 more idealised tracking scenario by correcting the cluster positions based on truth  
 425 information, and smearing the cluster position based on the detector resolution.

When pseudotracking is run alongside standard tracking, those clusters which are shared on the reconstructed tracks run through the cluster splitting machinery. If a cluster is found to be compatible with being split, its definition is changed, and the pseudotracks use this definition too. As a result, pseudotracks can have split clusters.

### 3.3 Investigating Improvements for High $p_T$ $B$ Tracking

An investigation into

#### 3.3.1 Looser Track Cuts & Track Refit Procedure

A solution for the problem of wrong inner-layer hits on  $B$  tracks had previously been developed. This solution selects tracks which pass a  $b$ -jet Region of Interest (ROI) selection, and then removes the innermost hits on these tracks based on the result of a “refit” procedure. The refit procedure runs as follows. Each track is refitted without the innermost hit, and if there is a significant improvement in the fit quality (the  $\chi^2$  of the track fit divided by the number of degrees of freedom on the track  $n$ ), the innermost hit is rejected and the new track replaces the old. If the fit quality does not improve by a certain amount, the initial track is kept. This procedure is recursively applied. The  $b$ -jet ROI selection selects tracks that are matched within  $dR < 0.14$  ( $|\eta| < 0.1$ ,  $|\phi| < 0.1$ ) of a CaloCluster with  $E_T > 150$  GeV. The track itself must also pass a transverse momentum cut with  $p_T > 15$  GeV. The refit procedure was previously shown to lead to a reduction in the rate of wrongly assigned IBL hits on  $B$  decay tracks (see fig. 3.8b). However, this apparent improvement did not lead to an increase in  $b$ -tagging performance. It was found that the refit procedure also removed unacceptable numbers of good hits, degrading the quality of un-problematic tracks, shown in fig. 3.8a. This is likely the cause of the underwhelming  $b$ -tagging performance improvement.

The performance of both the ROI, and the hit removal using track fit information, is examined, and an attempt at improving the performance of the refit procedure is made. Results are discussed in the following two sections.

### 3.3.2 Region of Interest Optimisation

Selection cuts for the  $b$ -jet ROI were determined on a largely ad-hoc basis. An effort was made to systematically optimise the selection cuts. The decay tracks of  $B$  hadrons are tightly collimated with the  $B$  itself, with most decay products satisfying  $dR(B, \text{track}) < 0.02$ , as shown in fig. 3.6a. Meanwhile, calorimeter clusters relating to the  $B$  hadrons are generally found within  $dR < 0.05$  of the  $B$  fig. 3.6b. In total, then,  $B$  decay tracks will usually be found within  $dR < 0.07$  of the relevant calorimeter cluster, which suggests that the current  $dR < 0.14$  is loose by a factor of two. Similar analysis of cluster and track energy distributions found that the related cuts were also loose, and so they were modified from  $E_T > 150$  GeV to  $E_T > 300$  GeV, and from  $p_T > 15$  GeV to  $p_T > 30$  GeV.

Additionally examined in the course of this work was the fake rate of the  $b$ -jet ROI. The distributions in fig. 3.7a demonstrate that most of clusters passing the  $E_T > 150$  GeV selection were unable to be matched to a nearby  $B$  hadron using truth information. Clusters that pass the selection but do not correspond to energy depositions from  $B$  hadrons lead to fake ROIs. As a consequence of these distributions, tracks selected by the ROI are largely impure in the desired  $B$  hadron tracks.

The modified ROI was used to re-run the refit procedure. A comparison of of “standard” and “optimised” (using the optimised  $b$ -jet ROI) refit procedures is found in fig. 3.8. These results show that whilst tighter selection cuts did lead to a recovery of some good hits (fig. 3.8a), performance with respect to the baseline is still significantly degraded.

a

b

**Figure 3.6:** Distributions of angular distance  $dR$  between  $B$  hadrons and their weak decays and other fragmentation tracks (fig. 3.6a), and the distribution of angular distance  $dR$  between  $B$  hadrons and the calorimeter clusters in the hadronic calorimeter (fig. 3.6b). In fig. 3.6a, the tracks from the weak decay of the  $B$  are significantly more collimated to the  $B$  than the other fragmentation tracks.

### 477 3.3.3 Fit Quality as a Discriminant for Wrong Hits

478 As mentioned, tracks selected by the ROI are refitted without their innermost hit,  
 479 and, if an improvement in fit quality is observed, the hit is rejected. In order to test  
 480 the effectiveness of this procedure, a dataset of two sets of tracks was produced. The  
 481 first set contained unmodified baseline-reconstructed tracks. The second contained  
 482 the same tracks as the first, but modifications made during reconstruction removed  
 483 the innermost hit on each track. Then, using Monte Carlo (MC) truth information,  
 484 a track-by-track fit quality comparison was made for tracks with good and wrong  
 485 innermost hits.

486 It is clear from the distributions in fig. 3.7b that the fit quality improvement (mea-  
 487 sured by fractional change in  $\chi^2/n$  of the track before and after the innermost hit  
 488 is removed) is not a discriminating variable for wrong hits, and indeed attempted  
 489 optimisations of the of the refit procedure based on these distributions were found  
 490 to be ineffectual. While wrong hits are likely to degrade the track fit, it is also true  
 491 that any additional measurement, good or wrong, constrains the track, and therefore  
 492 removal of that measurement will be likely to lead to an increase in the  $\chi^2/n$  of the  
 track. Removing hits in this way is therefore problematic.

a

b

**Figure 3.7:** The distribution of cluster transverse momentum, in fig. 3.7a for both clusters that were able (orange) and unable (blue) to be matched to a  $B$  hadron using MC truth information. The normalisation shows that the majority of clusters are not matched to  $B$  hadrons, resulting in fake ROIs. In fig. 3.7b, the fractional improvement in track fit quality ( $\chi^2/n$ ) is shown for all track (blue), tracks with good IBL hits (green), and tracks with wrong IBL hits (orange). The distributions are overlapping, suggesting that the  $\chi^2/n$  improvement is not a good discriminator of good and wrong hits.

493

### 494 3.3.4 Conclusion

495 The work outlined in the two preceding sections has uncovered issues with both the  
 496  $b$ -jet ROI, and the methodology of identification and removal of wrong hits on tracks  
 497 inside a given ROI. Attempts were made to optimise the selection cuts of the ROI,  
 498 however the large background of energetic phenomena produced in collisions that

are not  $B$  hadron related means that the ROI is largely unsuccessful in selecting a pure sample of likely  $B$  hadron candidates. An additional effort was made to improve the removal of wrong hits using other information in addition to the track fit improvement. Information such as the type and locations of its, and track  $d_0$  were considered. While progress here was not insignificant, without substantial overhaul of the ROI to improve  $B$  purity, the results were not strong enough to demonstrate any viable solutions that would successfully target and then improve  $B$  hadron decay tracks. Alongside the refit procedure, a “Bcut” cut scheme was suggested in order

a b

**Figure 3.8:** Distributions of good (fig. 3.8a) and wrong (fig:refit optimisation results sub2) hit assignment rates on the IBL for tracks using baseline tracking (black), the original unmodified refit procedure (green), and the refit procedure with an optimised set of ROI selection cuts (blue). The IBL lies at a radius of 33 mm from the beam pipe. Hence, particles produced with a production radius greater than this cannot leave good hits on the IBL.

to improve reconstruction performance. This consisted primarily of loosening the shared hit cuts in the ambiguity solver. While this did lead to a measurement increase in track reconstruction efficiency (see fig. 3.4), it was determined that the corresponding increase in fake tracks (i.e. those tracks for which the majority of hits do not come from a single truth particle) was too large to justify the implementation of the “Bcut” scheme. In conclusion, then, a different approach is required to address the problems discussed.

### 3.4 Global $\chi^2$ Fitter Outlier Removal

This section documents ongoing progress into improving hit assignments using the Global  $\chi^2$  Fitter (GX2F) to prevent wrong hits from being assigned to tracks during the track fit. This is in contrast to the approach discussed in `refit`, which attempts to identify and remove wrong hits after the reconstruction of the track (of which the track fit is a part). As part of the track fit, an outlier removal procedure is run, in which suspicious hits are identified and removed. The GX2F code, as a relatively low-level component of track reconstruction, has not undergone significant modification for several years. During this time, a new tracking sub-detector, the

IBL, was installed, and subsequently precise detector alignments have been derived. The motivation for looking at the GX2F is that these changes may require re-optimisation of the GX2F code, and in particular the outlier removal procedures. Further motivation for this approach comes from the low rate of labelled outliers in baseline tracking. For example, while approximately 15% of  $B$  hadron decay tracks have a wrong IBL hit (a value which only increases with the  $p_T$  of the  $B$ ), less than 1% of this tracks have had their IBL hit labelled and removed as an outlier.

## Implementation

The outlier removal procedure for the pixel detector is described in this section. The states (also called measurements, or hits) on the track are looped over in order of increasing radial distance to the beam pipe. For each state, errors  $\sigma(m_i)$  on the measurement of the transverse and longitudinal coordinates are calculated. These errors are dependent on the sub-detector which recorded the measurement (as some sub-detectors are more precise than others). Additionally, a residual displacement  $r_i$  between the predicted position of the track  $x_i$  (inclusive of the current measurement), and the position of the measurement itself,  $m_i$ , is calculated. The pull  $p_i$  on the track state due to the current measurement is calculated according to

$$p_i = \frac{m_i - x_i}{\sqrt{\sigma(m_i)^2 - \sigma(x_i)^2}}, \quad r_i = m_i - x_i. \quad (3.1)$$

This pull is computed for the transverse and longitudinal coordinates of the measurement, and the maximum of the two is selected and checked to see if it exceeds a certain threshold. If it does, the hit will be removed, after some additional checks are made to confirm or deny the presence of the outlier. The threshold is set as a member variable `m_outcut`. The results of varying this cut are described in section 3.4.1.

### 3.4.1 Cut Optimisation

A systematic variation of the cut point `m_outcut` has been carried out. The results, demonstrating a reduction in wrong hit assignment whilst keeping virtually all good hits assigned to tracks, are shown in fig. 3.9. The rate of wrong hits assigned to

541 tracks decreases from 0.32 to 0.28 at the highest energies (12.5% reduction). More-  
 542 over, this result is obtained looking at all tracks inclusively, and the demonstrated  
 543 improvement removes the need for a specific  $b$ -jet ROI (a requirement which led to  
 544 problems outlined in section 3.3.2). These results hold when looking exclusively at  
 $B$  decay tracks. The fact that, as shown in fig. 3.8a, virtually all correctly assigned

a

b

**Figure 3.9:** Profiles, as a function of parent  $B$  hadron  $p_T$ , of good (fig. 3.9a) and wrong (fig. 3.9b) hit assignment rates on the IBL for tracks using baseline tracking (black), and various looser values of the outlier cut.

545 hits are retained suggests that it may possible to relax this cut further. Tests are  
 546 ongoing which will confirm this. The current GX2F treats all layers in the pixel  
 547 detector in the same way - applying the same cut to each. While fig. 3.8a shows no  
 548 adverse affects for hits on the IBL, when relaxing `m_outlcut` to a value of 1, some  
 549 small reduction in good hit assignment efficiency was observed in other layers of the  
 550 pixel detector, which are less precise. This difference in precision motivates the need  
 551 to treat different layers in the pixel detector differently. To this end, layer-specific  
 552 cutting capabilities for the GX2F are under development, which will allow each pixel  
 553 layer to have their own cut point for outlier removal. Layer specific cuts will then  
 554 be optimised to see if greater numbers of wrong hits can be successfully identified  
 555 as outliers and removed, while maintaining high good hit assignment efficiency.

## Chapter 5

# Graph Neural Network Flavour Tagger

Flavour tagging, the identification of jets originating from  $b$ - and  $c$ -quarks, is a critical component of the physics programme of the ATLAS experiment at the Large Hadron Collider. Current flavour tagging algorithms rely on the outputs of several low-level algorithms, which reconstruct various properties of jets using charged particle tracks, that are then combined using machine learning techniques. In this note a new machine learning algorithm based on graph neural networks, GN1, is introduced. GN1 uses information from a variable number of charged particle tracks within a jet, to predict the jet flavour without the need for intermediate low-level algorithms. Alongside the jet flavour prediction, the model predicts which physics processes produced the different tracks in the jet, and groups tracks in the jet into vertices. These auxiliary training objectives provide useful additional information on the contents of the jet and improve performance. GN1 compares favourably with the current ATLAS flavour tagging algorithms. For a  $b$ -jet efficiency of 70%, the light ( $c$ )-jet rejection is improved by a factor of  $\sim 1.8$  ( $\sim 2.1$ ) for jets coming from  $t\bar{t}$  decays with transverse momentum  $20 < p_T < 250$  GeV. For jets coming from  $Z'$  decays with transverse momentum  $250 < p_T < 5000$  GeV, the light ( $c$ )-jet rejection improves by a factor  $\sim 6$  ( $\sim 2.8$ ) for a comparative 30%  $b$ -jet efficiency.

## 5.1 Motivation

Flavour tagging, the identification of jets originating from  $b$ - and  $c$ -quarks, is a critical component of the physics programme of the ATLAS experiment [21] at the Large Hadron Collider (LHC) [28]. It is of particular importance for the study of the Standard Model (SM) Higgs boson and the top quark, which preferentially decay to  $b$ -quarks [29, 30], and additionally for several Beyond Standard Model (BSM) resonances that readily decay to heavy flavour quarks [31]. The significant lifetime of  $b$ -hadrons, approximately 1.5 ps [32], provides the unique signature of a secondary decay vertex which has a high mass and is significantly displaced from the primary vertex. Additional signatures of  $b$ -hadrons are the tertiary decay vertex, resulting from  $b \rightarrow c$  decay chains, and the reconstructed trajectories of charged particles (henceforth simply referred to as tracks) with large impact parameters<sup>1</sup> (IPs). These signatures are primarily identified using tracks associated to jets. As such, efficient and accurate track reconstruction is essential for high performance flavour tagging.

This note introduces a novel algorithm, GN1, which uses Graph Neural Networks (GNNs) [33] with auxiliary training objectives, to aid the primary goal of classifying whether jets originate from  $b$ - or  $c$ -quarks (referred to as a flavour tagger). The concept is illustrated in fig. 5.1. The use of GNNs offers a natural way to classify jets with variable numbers of unordered associated tracks, while allowing for the inclusion of auxiliary training objectives [34, 35].

The current ATLAS flavour tagger, DL1r [36], is a deep neural network which takes the outputs of a number of independently optimised “low-level” algorithms [37] as inputs. Each of these low-level algorithms makes use of tracks to reconstruct a particular aspect of the experimental signature of heavy flavour jets. The low-level algorithms can be manually optimised reconstruction algorithms, for example the SV1 and JetFitter algorithms that reconstruct displaced decay vertices, or trained taggers such as RNNIP and DIPS that use the IPs of a variable number of tracks to identify the flavour of the jet [22, 37–39]. In contrast GN1 utilises a single neural network, which directly takes the tracks and some information about the jet as inputs. As such, it does not depend on any other flavour tagging algorithm, and a single training of the GN1 fully optimises all aspects of the algorithm.

---

<sup>1</sup>The distance of closest approach from a track to the primary vertex.

**Figure 5.1:** Comparison of the existing flavour tagging scheme (left) and GN1 (right). The existing approach utilises low-level algorithms (shown in blue), the outputs of which are fed into a high-level algorithm (DL1r). Instead of being used to guide the design of the manually optimised algorithms, additional truth information from the simulation is now being used as auxiliary training targets for GN1. The solid lines represent reconstructed information, whereas the dashed lines represent truth information.

GN1 is trained to understand the internal structure of the jet through the use of two auxiliary training objectives: the grouping of tracks originating from a common vertex, and the prediction of the underlying physics process from which each track originated. These auxiliary objectives are meant to guide the neural network towards a more complete understanding of the underlying physics, removing the need for the low-level algorithms, and therefore simplifying the process of optimising the tagger for new regions of phase space (e.g.  $c$ -tagging or high- $p_T$   $b$ -tagging), or when the detector or charged particle reconstruction algorithms are updated. The training targets for the primary and auxiliary objectives are extracted from “truth information”, i.e. information only available in simulation, as opposed to reconstructed quantities available in both collision data and simulation.

In this note, the following benefits of this approach will be shown:

1. Improved performance with respect to the current ATLAS flavour tagging algorithms, with larger background rejection for a given signal efficiency.
2. The same network architecture can be easily optimised for a wider variety of use cases (e.g.  $c$ -jet tagging and high- $p_T$  jet tagging), since there are no low-level algorithms to retune.
3. There are fewer flavour tagging algorithms to maintain.
4. Alongside the network’s prediction of the jet flavour, the auxiliary vertex and track origin predictions provide more information on why a jet was (mis)tagged or not. This information can also have uses in other applications, for instance to explicitly reconstruct displaced decay vertices or to remove fake tracks.<sup>2</sup>

This note is organised as follows: a brief description of the ATLAS detector, object definitions and selections, and samples are provided in section 5.3; details about the model architecture and training procedure are given in section 5.4; and results are discussed in section 5.5.

---

<sup>2</sup>A fake track is defined as a track with a truth-matching probability less than 0.5, where the truth-matching probability is defined in Ref. [23].

## 5.2 Graph Neural Network Theory

## 5.3 Experimental Setup

### 5.3.1 Datasets

To train and evaluate the model, simulated SM  $t\bar{t}$  and BSM  $Z'$  events initiated by proton-proton collisions at a center of mass energy  $\sqrt{s} = 13 \text{ TeV}$  are used. The  $Z'$  sample is constructed in such a manner that it has a relatively flat jet  $p_T$  spectrum up to 5 TeV and decays to an equal numbers of  $b$ -,  $c$ - and light- jets. The generation of the simulated event samples includes the effect of multiple  $pp$  interactions per bunch crossing with an average pileup of  $\langle\mu\rangle = 40$ , which includes the effect on the detector response due to interactions from bunch crossings before or after the one containing the hard interaction.

The  $t\bar{t}$  events are generated using the POWHEGBOX [40–43] v2 generator at next-to-leading order with the NNPDF3.0NLO [44] set of parton distribution functions (PDFs). The  $h_{\text{damp}}$  parameter<sup>3</sup> is set to 1.5 times the mass of the top-quark ( $m_{\text{top}}$ ) [45], with  $m_{\text{top}} = 172.5 \text{ GeV}$ . The events are interfaced to PYTHIA 8.230 [46] to model the parton shower, hadronisation, and underlying event, with parameters set according to the A14 tune [47] and using the NNPDF2.3LO set of PDFs [48].  $Z'$  events are generated with PYTHIA 8.2.12 with the same tune and PDF set. The decays of  $b$ - and  $c$ -hadrons are performed by EVTGEN v1.6.0 [49]. Particles are passed through the ATLAS detector simulation [50] based on GEANT4 [51].

For the  $t\bar{t}$  events, at least one  $W$  boson from the top quark decay is required to decay leptonically. Truth labelled  $b$ -,  $c$ - and light- jets are kinematically re-sampled in  $p_T$  and  $\eta$  to ensure identical distributions in these variables. The resulting dataset contains 30 million jets, 60% of which are  $t\bar{t}$  jets and 40% of which are  $Z'$  jets. While DL1r uses 70%  $t\bar{t}$  jets and 30%  $Z'$  jets, the change in sample composition did not affect the final performance of GN1. To evaluate the performance of the model, 500k jets from both the  $t\bar{t}$  and  $Z'$  samples, which are statistically independent from the

---

<sup>3</sup>The  $h_{\text{damp}}$  parameter is a resummation damping factor and one of the parameters that controls the matching of POWHEG matrix elements to the parton shower and thus effectively regulates the high- $p_T$  radiation against which the  $t\bar{t}$  system recoils.

training sample, are used. Track- and jet-level inputs are scaled to have a central value of zero and a variance of unity before training and evaluation.

## 5.4 Model Architecture

### 5.4.1 Model Inputs

GN1 is given two jet variables and 21 tracking related variables for each track fed into the network. The jet transverse momentum and signed pseudorapidity constitute the jet-level inputs, with the track-level inputs listed in table 5.1. If a jet has more than 40 associated tracks, the first 40 tracks with the largest transverse IP significance<sup>4</sup>  $s(d_0)$  are selected as inputs. Full track parameter information and associated uncertainties, along with detailed hit information, carry valuable information about the jet flavour. In the dense cores of high- $p_T$  jets, tracks are highly collimated and separation between tracks can be of the same order as the active sensor dimensions, resulting in merged clusters and tracks which share hits [23]. Due to the relatively long lifetimes of  $b$ -hadrons and  $c$ -hadrons, which can traverse several layers of the ID before decaying and have highly collimated decay products, the presence of shared or missing hits is a critical signature of heavy flavour jets.

Dependence on the absolute value of the azimuthal jet angle  $\phi$  is explicitly removed by providing only the azimuthal angle of tracks relative to the jet axis. The track pseudorapidity is also provided relative to the jet axis.

Since heavy flavour hadrons can decay semileptonically, the presence of a reconstructed lepton in the jet carries discriminating information about the jet flavour. In addition to the baseline GN1 model, the GN1 Lep variant includes an additional track-level input, leptonID, which indicates if the track was used in the reconstruction of an electron, a muon or neither. The muons are required to be combined [53], and the electrons are required to pass the *VeryLoose* likelihood-based identification working point [54].

---

<sup>4</sup>Impact parameter significances are defined as the IP divided by its corresponding uncertainty,  $s(d_0) = d_0/\sigma(d_0)$  and  $s(z_0) = z_0/\sigma(z_0)$ . Track IP significances are lifetime signed according to the track's direction with respect to the jet axis and the primary vertex [52].

**Table 5.1:** Input features to the GN1 model. Basic jet kinematics, along with information about the reconstructed track parameters and constituent hits are used. Shared hits, are hits used on multiple tracks which have not been classified as split by the cluster-splitting neural networks [23], while split hits are hits used on multiple tracks which have been identified as merged. A hole is a missing hit, where one is expected, on a layer between two other hits on a track. The track leptonID is an additional input to the GN1 Lep model.

Jet Input	Description
$p_T$	Jet transverse momentum
$\eta$	Signed jet pseudorapidity
Track Input	Description
$q/p$	Track charge divided by momentum (measure of curvature)
$d\eta$	Pseudorapidity of the track, relative to the jet $\eta$
$d\phi$	Azimuthal angle of the track, relative to the jet $\phi$
$d_0$	Closest distance from the track to the PV in the longitudinal plane
$z_0 \sin \theta$	Closest distance from the track to the PV in the transverse plane
$\sigma(q/p)$	Uncertainty on $q/p$
$\sigma(\theta)$	Uncertainty on track polar angle $\theta$
$\sigma(\phi)$	Uncertainty on track azimuthal angle $\phi$
$s(d_0)$	Lifetime signed transverse IP significance
$s(z_0)$	Lifetime signed longitudinal IP significance
nPixHits	Number of pixel hits
nSCTHits	Number of SCT hits
nIBLHits	Number of IBL hits
nBLHits	Number of B-layer hits
nIBLShared	Number of shared IBL hits
nIBLSplit	Number of split IBL hits
nPixShared	Number of shared pixel hits
nPixSplit	Number of split pixel hits
nSCTShared	Number of shared SCT hits
nPixHoles	Number of pixel holes
nSCTHoles	Number of SCT holes
leptonID	Indicates if track was used to reconstruct an electron or muon

## 5.4.2 Auxiliary Training Objectives

In addition to the jet flavour classification, two auxiliary training objectives are defined. Each auxiliary training objective comes with a training target which, similar to the jet flavour label, are truth labels derived from the simulation. The presence of the auxiliary training objectives improves the jet classification performance as demonstrated in section 5.5.3.

The first auxiliary objective is the prediction of the origin of each track within the jet. Each track is labelled with one of the exclusive categories defined in table 5.2 after analysing the particle interaction that led to its formation. Since the presence of different track origins is strongly related to the flavour of the jet, training GN1 to recognise the origin of the tracks may provide an additional handle on the classification of the jet flavour. This task may also aid the jet flavour prediction by acting as a form of supervised attention [55] - in detecting tracks from heavy flavour decays the model may learn to pay more attention to these tracks.

**Table 5.2:** Truth origins which are used to categorise the physics process that led to the production of a track. Tracks are matched to charged particles using the truth-matching probability [23]. A truth-matching probability of less than 0.5 indicates that reconstructed track parameters are likely to be mismeasured and may not correspond to the trajectory of a single charged particle. The “OtherSecondary” origin includes tracks from photon conversions,  $K_S^0$  and  $\Lambda^0$  decays, and hadronic interactions.

Truth Origin	Description
Pileup	From a $pp$ collision other than the primary interaction
Fake	Created from the hits of multiple particles
Primary	Does not originate from any secondary decay
fromB	From the decay of a $b$ -hadron
fromBC	From a $c$ -hadron decay, which itself is from the decay of a $b$ -hadron
fromC	From the decay of a $c$ -hadron
OtherSecondary	From other secondary interactions and decays

Displaced decays of  $b$ - and  $c$ -hadrons lead to secondary and tertiary vertices inside the jet. Displaced secondary vertices can also occur in light-jets as a result of material interactions and long-lived particle decays (e.g.  $K_S^0$  and  $\Lambda^0$ ). The second auxiliary objective is the prediction of track-pair vertex compatibility. For each pair

of tracks in the jet, GN1 predicts a binary label, which is given a value 1 if the two tracks in the pair originated from the same point in space, and 0 otherwise. To derive the corresponding truth labels for training, truth production vertices within 0.1 mm are merged. Track-pairs where one or both of the tracks in the pair have an origin label of either Pileup or Fake are given a label of 0. Using the pairwise predictions from the model, collections of commonly compatible tracks can be grouped into vertices. The addition of this auxiliary training objective removes the need for inputs from a dedicated secondary vertexing algorithm.

Both auxiliary training objectives can be considered as “stepping stones” on the way to classifying the flavour of the jet. By requiring the model to predict the truth origin of each track and the vertex compatibility of each track-pair, the model is guided to learn representations of the jet which are connected to the underlying physics and therefore relevant for classifying the jet flavour.

### 5.4.3 Architecture

As discussed above, the GN1 model combines a graph neural network architecture [56] with auxiliary training objectives in order to determine the jet flavour. Coarse optimisation of the network architecture hyperparameters, for example number of layers and number of neurons per layer, has been carried out to maximise the tagging efficiency.

The model architecture is based on a previous implementation of a graph neural network jet tagger [35]. As compared to the previous approach, GN1 uses a only a single graph neural network and makes use of a more sophisticated graph neural network layer [57], described below. These changes yield improved tagging performance and a significant reduction in training time with respect to the previous approach.

The model takes jet- and track-level information as inputs, as detailed in section 5.4.1. The jet inputs are concatenated with each track’s inputs, as shown in fig. 5.2. The combined jet-track vectors are then fed into a per-track initialisation network with three hidden layers, each containing 64 neurons, and an output layer with a size of 64, as shown in fig. 5.3. The track initialisation network is similar to a Deep Sets model [58], but does not include a reduction operation (mean or summation) over the output track representations.

chapters/gnn\_tagger/figs/inputs\_diagram.png

**Figure 5.2:** The inputs to GN1 are the two jet features ( $n_{\text{jf}} = 2$ ), and an array of  $n_{\text{tracks}}$ , where each track is described by 21 track features ( $n_{\text{tf}} = 21$ ). The jet features are copied for each of the tracks, and the combined jet-track vectors of length 23 form the inputs of GN1.

chapters/gnn\_tagger/figs/full\_arch.pdf

**Figure 5.3:** The network architecture of GN1. Inputs are fed into a per-track initialisation network, which outputs an initial latent representation of each track. These representations are then used to populate the node features of a fully connected graph network. After the graph network, the resulting node representations are used to predict the jet flavour, the track origins, and the track-pair vertex compatibility.

755 A fully connected graph is built from the outputs of the track initialisation net-  
 756 work, such that each node in the graph neighbours every other node. Each node  
 757  $h_i$  in the graph corresponds to a single track in the jet, and is characterised by a  
 758 feature vector, or representation. The per-track output representations from the  
 759 initialisation networks are used to populate the initial feature vectors of each node  
 760 in the graph. In each layer of the graph network, output node representations  $h'_i$  are  
 761 computed by aggregating the features of  $h_i$  and neighbouring nodes  $\mathcal{N}_i$  as described  
 762 in Ref. [57]. First, the feature vectors of each node are fed into a fully connected  
 763 layer  $\mathbf{W}$ , to produce an updated representation of each node  $\mathbf{W}h_i$ . These updated  
 764 feature vectors are used to compute edge scores  $e(h_i, h_j)$  for each node pair,

$$e(h_i, h_j) = \mathbf{a}^\top \theta [\mathbf{W}h_i \oplus \mathbf{W}h_j], \quad (5.1)$$

765 where  $\oplus$  denotes vector concatenation,  $\theta$  is a non-linear activation function, and  
 766  $\mathbf{a}$  is a second fully connected layer. These edge scores are then used to calculate  
 767 attention weights  $a_{ij}$  for each pair of nodes using the softmax function over the edge  
 768 scores

$$a_{ij} = \text{softmax}_j [e(h_i, h_j)]. \quad (5.2)$$

769 Finally, the updated node representation  $h'_i$  is computed by taking the weighted sum  
 770 over each updated node representation  $\mathbf{W}h_i$ , with weights  $a_{ij}$

$$h'_i = \sigma \left[ \sum_{j \in \mathcal{N}_i} a_{ij} \cdot \mathbf{W}h_j \right]. \quad (5.3)$$

771 The above set of operations constitute a single graph network layer. Three such  
 772 layers are stacked to construct the graph network, representing a balance between  
 773 achieving optimal performance and preventing overtraining. The final output node  
 774 feature vectors from the network are representations of each track that are condi-

775 tional on the other tracks in the jet. The output representation for each track is  
 776 combined using a weighted sum to construct a global representation of the jet, where  
 777 the attention weights for the sum are learned during training. Three separate fully  
 778 connected feedforward neural networks are then used to independently perform the  
 779 different classification objectives of GN1. Each of the objectives makes use of the  
 780 global representation of the jet. A summary of the different classification networks  
 781 used for the various training objectives is shown in table 5.3.

**Table 5.3:** A summary of GN1’s different classification networks used for the different training objectives. The hidden layers column contains a list specifying the number of neurons in each layer.

Network	Hidden layers	Output size
Node classification network	128, 64, 32	7
Edge classification network	128, 64, 32	1
Graph classification network	128, 64, 32, 16	3

782 A node classification network, which takes as inputs the features from a single output  
 783 node from the graph network and the global jet representation, predicts the track  
 784 truth origin, as defined in table 5.2. This network has three hidden layers containing  
 785 128, 64 and 32 neurons respectively, and an output size of seven, corresponding to  
 786 the seven different truth origins.

787 An edge classification network, which takes as inputs the concatenated representa-  
 788 tions from each pair of tracks and the global jet representation, is used to predict  
 789 whether the tracks in the track-pair belong to a common vertex. The edge network  
 790 has three hidden layers containing 128, 64 and 32 neurons respectively, and a single  
 791 output, which is used to perform binary classification of the track-pair compata-  
 792 bility. These predictions are used for the auxiliary training objectives discussed in  
 793 section 5.4.2.

794 A graph classification network takes only the global jet representation as an input,  
 795 and predicts the jet flavour. The graph classification network is comprised of four  
 796 fully connected hidden layers with 128, 64, 32 and 16 neurons respectively, and has  
 797 three outputs corresponding to the  $b$ -,  $c$ - and light- jet classes.

#### 5.4.4 Training

The full GN1 training procedure minimises the total loss function  $L_{\text{total}}$ , defined in eq. (5.4). This loss is composed of three terms:  $L_{\text{jet}}$ , the categorical cross entropy loss over the different jet flavours;  $L_{\text{vertex}}$ , the binary track-pair compatability cross entropy loss averaged over all track-pairs; and  $L_{\text{track}}$ , the categorical cross entropy loss for the track origin prediction.  $L_{\text{vertex}}$  is computed by averaging over all track-pairs in the batch, and  $L_{\text{track}}$  is computed by averaging over all tracks in the batch.

$$L_{\text{total}} = L_{\text{jet}} + \alpha L_{\text{vertex}} + \beta L_{\text{track}} \quad (5.4)$$

The different losses converge to different values during training, reflective of differences in the relative difficulty of the various objectives. As such,  $L_{\text{vertex}}$  and  $L_{\text{track}}$  are weighted by  $\alpha = 1.5$  and  $\beta = 0.5$  respectively to ensure they converge to similar values, giving them an equal weighting towards  $L_{\text{total}}$ . The values of  $\alpha$  and  $\beta$  also ensure that  $L_{\text{jet}}$  converges to a larger value than  $L_{\text{vertex}}$  and  $L_{\text{track}}$ , reflecting the primary importance of the jet classification objective. In practice, the final performance of the model was not sensitive to modest variations in the loss weights  $\alpha$  and  $\beta$ , or to pre-training using  $L_{\text{total}}$  and fine tuning on the jet classification task only. As there was a significant variation in the relative frequency of tracks of different origins, the contribution of each origin class to  $L_{\text{track}}$  was weighted by the inverse of the frequency of their occurrence. In  $L_{\text{vertex}}$ , the relative class weight in the loss for track-pairs where both tracks are from either a  $b$ - or  $c$ -hadron is increased by a factor of two as compared with other track-pairs.

The track classification and vertexing objectives are supplementary to the jet classification objective and trainings can be performed with either the node or edge networks, or both, removed, as discussed in section 5.5.3. In these cases, the corresponding losses  $L_{\text{vertex}}$  and  $L_{\text{track}}$  are removed from the calculation of  $L_{\text{total}}$ . The resulting trainings demonstrate how useful the different auxiliary training objectives are for the primary jet classification objective.

GN1 trainings are run for 100 epochs on 4 NVIDIA V100 GPUs, taking around 25 mins to complete each epoch over the training sample of 30 million jets described in section 5.3.1. The Adam optimiser [59] with an initial learning rate of  $1e-3$ ,

and a batch size of 4000 jets (spread across the 4 GPUs) was used. Typically the validation loss, calculated on 500k jets, stabilised after around 60 epochs. The epoch that minimized the validation loss was used for evaluation. GN1 has been integrated into the ATLAS software [60] using ONNX [61], and jet flavour predictions for the test sample are computed using the ATLAS software stack.

## 5.5 Results

The performance of the GN1 tagger is evaluated for both  $b$ -tagging and  $c$ -tagging use cases, and for both jets with  $20 < p_T < 250$  GeV from the  $t\bar{t}$  sample and jets with  $250 < p_T < 5000$  GeV from the  $Z'$  sample. Performance is compared to the DL1r tagger [36], which has been retrained on 75 million jets from the same samples as GN1. The input RNNIP tagger [39] to DL1r has not been retrained.

The taggers predict the probability that a jet belongs to the  $b$ -,  $c$ - and light- classes. To use the model for  $b$ -tagging, these probabilities are combined into a single score  $D_b$ , defined as

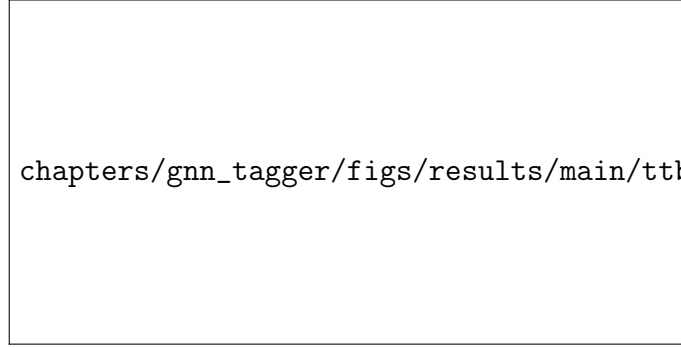

$$D_b = \log \frac{p_b}{(1 - f_c)p_l + f_c p_c}, \quad (5.5)$$

where  $f_c$  is a free parameter that determines the relative weight of  $p_c$  to  $p_l$  in the score  $D_b$ , controlling the trade-off between  $c$ - and light-jet rejection performance. This parameter is set to a value of  $f_c = 0.018$  for the DL1r model, obtained through an optimisation procedure designed to maximise the  $c$ - and light-jet rejection of DL1r [36]. For the GN1 models a value of  $f_c = 0.05$  is used, based on a similar optimisation procedure. The choice of  $f_c$  is arbitrary, with the different optimised values reflecting the relative  $c$ - versus light-jet rejection performance of the various taggers. A fixed-cut working point (WP) defines the corresponding selection applied to the tagging discriminant  $D_b$  in order to achieve a given inclusive efficiency on the  $t\bar{t}$  sample.

The technical implementation of GN1 results in any jet with no associated tracks or exactly one associated track to be classified as a light-jet. The impact of this on the

853 tagging performance of GN1 was found to be negligible, with 0.12% of  $b$ -jets in the  
 854  $t\bar{t}$  sample and 0.02% of  $b$ -jets in the  $Z'$  sample affected. Of those, 89% of the  $b$ -jets  
 855 in the  $t\bar{t}$  sample and 98% of the  $b$ -jets in the  $Z'$  sample are classified as light-jets by  
 856 DL1r at the 70%  $t\bar{t}$  WP.

857 A comparison of the  $b$ -tagging discriminant  $D_b$  between DL1r and GN1 is given in  
 858 fig. 5.4. The shapes of the distributions are broadly similar for  $b$ -,  $c$ - and light-  
 859 jets, however, the GN1 model shifts the  $b$ -jet distribution to higher values of  $D_b$  in  
 860 the regions with the best discrimination. The GN1  $c$ -jet distribution is also shifted  
 861 to lower values of  $D_b$  when compared with DL1r, enhancing the separation and  
 862 indicating that GN1 will improve  $c$ -jet rejection when compared with DL1r.

**Figure 5.4:** Comparison between the DL1r and GN1  $b$ -tagging discriminant  $D_b$  for jets in the  $t\bar{t}$  sample. The 85% WP and the 60% WP are marked by the solid (dashed) lines for GN1 (DL1r), representing respectively the loosest and tightest WPs used by analyses. A value of  $f_c = 0.018$  is used in the calculation of  $D_b$  for DL1r and  $f_c = 0.05$  is used for GN1. The distributions of the different jet flavours have been normalised to unity area.

### 863 5.5.1 $b$ -tagging Performance

864 The performance of a  $b$ -tagging algorithm is quantified by its power to reject  $c$ -  
 865 and light-jets for a given  $b$ -jet tagging efficiency, or WP. In order to compare the  
 866  $b$ -tagging performance of the different taggers for the  $b$ -jet tagging efficiencies in the  
 867 range typically used by analyses, the corresponding  $c$ - and light-jet rejection rates  
 868 are displayed in figs. 5.5 and 5.6 for jets in the  $t\bar{t}$  and  $Z'$  samples respectively. Four  
 869 standard WPs with  $b$ -jet tagging efficiencies of 60%, 70%, 77% and 85% are used  
 870 by physics analyses depending on their specific signal and background requirements.  
 871 These WPs are defined using jets in the  $t\bar{t}$  sample only. The  $b$ -jet tagging efficiencies

for jets in the  $Z'$  sample are lower than the corresponding WPs calculated in the  $t\bar{t}$  sample, due to the much higher jet  $p_T$  range in the  $Z'$  sample. For instance the WP defined to provide a 70%  $b$ -jet tagging efficiency on the  $t\bar{t}$  sample results in a  $b$ -jet tagging efficiency of  $\sim 30\%$  on the  $Z'$  sample. To account for this, the range of  $b$ -jet tagging efficiencies displayed in fig. 5.6 is chosen to span the lower values achieved in the  $Z'$  sample.

For jets in the  $t\bar{t}$  sample with  $20 < p_T < 250$  GeV, GN1 demonstrates considerably better  $c$ - and light-jet rejection compared with DL1r across the full range of  $b$ -jet tagging efficiencies probed. The relative improvement depends on the  $b$ -jet tagging efficiency, with the largest improvements found at lower values. At a  $b$ -jet tagging efficiency of 70%, the  $c$ -rejection improves by a factor of  $\sim 2.1$  and the light-jet rejection improves by a factor of  $\sim 1.8$  with respect to DL1r. For high- $p_T$  jets in the  $Z'$  sample with  $250 < p_T < 5000$  GeV, GN1 also brings considerable performance improvements with respect to DL1r across the range of  $b$ -jet tagging efficiencies studied. Again, the largest relative improvement in performance comes at lower  $b$ -jet tagging efficiencies. At a  $b$ -jet tagging efficiency of 30%, GN1 improves the  $c$ -rejection by a factor of  $\sim 2.8$  and the light-jet rejection by a factor of  $\sim 6$ . An increasing statistical uncertainty due to the high rejection of background affects the comparison at lower  $b$ -jet tagging efficiencies. It is estimated that for a  $b$ -jet tagging efficiency of 70% in the  $t\bar{t}$  sample,  $\sim 5\%$  ( $\sim 30\%$ ) of the relative improvement in the  $c$ -jet (light-jet) rejection comes from loosening the track selection and for a  $b$ -jet tagging efficiency of 30% in the  $Z'$  the corresponding number is  $\sim 10\%$  for both  $c$ -jets and light-jets. Given the sophisticated exploitation of low-level information, further studies are needed to confirm if the performance gain is also observed in experimental data.

The GN1 Lep variant shows improved performance with respect to the baseline GN1 model, demonstrating the additional jet flavour discrimination power provided by the leptonID track input. For jets in the  $t\bar{t}$  sample, the relative  $c$ -rejection improvement with respect to DL1r at the 70%  $b$ -jet WP increases from a factor of  $\sim 2.1$  for GN1 to a factor of  $\sim 2.8$  for GN1 Lep. The improvement in light-jet rejection also increases from a factor of  $\sim 1.8$  to  $\sim 2.5$  at this WP. For jets in the  $Z'$  sample, the relative  $c$ -rejection (light-jet rejection) improvement with respect to DL1r increases from a factor of  $\sim 2.8$  to  $\sim 3$  ( $\sim 6$  to  $\sim 7.5$ ) at a  $b$ -jet tagging efficiency

905 of 30%. As shown in fig. 5.7, the greatest improvement of GN1 Lep over GN1 is  
 906 seen at low  $p_T$ .

907 The performance of the taggers is strongly dependent on the jet  $p_T$ . Charged particle  
 908 reconstruction is particularly challenging within high- $p_T$  jets [23]. The multiplicity of  
 909 fragmentation particles increases as a function of  $p_T$ , while the number of particles  
 910 from heavy flavour decays stays constant. Collimation of particles inside the jet  
 911 increases and approaches the granularity of the tracking detectors, making it difficult  
 912 to resolve the trajectories of different particles. Furthermore, at high  $p_T$ , heavy  
 913 flavour hadrons will travel further into the detector before decaying. For hadrons  
 914 which traverse one or more layers of the ID before decaying, the corresponding decay  
 915 tracks may pick up incorrect hits, left by the hadron itself or fragmentation particles,  
 916 in the inner layers of the detector, reducing the accuracy of the reconstructed track  
 917 parameters. These factors contribute to a reduced reconstruction efficiency for heavy  
 918 flavour tracks, and a general degradation in quality of tracks inside the core of a jet,  
 919 which in turn reduces the jet classification performance.

920 In order to study how the  $b$ -jet tagging efficiency of the taggers varies as a function  
 921 of jet  $p_T$ , the  $b$ -jet tagging efficiency as a function of  $p_T$  for a fixed light-jet rejection  
 922 of 100 in each bin is shown in fig. 5.7. For jets in the  $t\bar{t}$  sample, at a fixed light-jet  
 923 rejection of 100, GN1 improves the  $b$ -jet tagging efficiency by approximately 4%  
 924 across all jet  $p_T$  bins. GN1 Lep shows improved performance with respect to GN1,  
 925 in particular at lower  $p_T$ , with the relative increase in the  $b$ -jet tagging efficiency  
 926 going from 4% to 8%. For jets in the  $Z'$  sample, GN1 has a higher  $b$ -jet tagging  
 927 efficiency than DL1r across the  $p_T$  range, with the largest relative improvement in  
 928 performance, approximately a factor of 2, found at jet  $p_T > 2$  TeV. GN1 outperforms  
 929 DL1r across the entire jet  $p_T$  spectrum studied. The performance was also evaluated  
 930 as a function of the average number of pileup interactions in an event, and was found  
 931 to have no significant dependence on this quantity.

## 932 5.5.2 $c$ -tagging Performance

933 Since GN1 does not rely on any manually optimised low-level tagging algorithms,  
 934 which may not have been optimised for  $c$ -tagging, tagging  $c$ -jets presents a com-  
 935 pelling use case for GN1. To use the model for  $c$ -tagging, the output probabilities  
 936 are combined into a single score  $D_c$ , defined similarly to eq. (5.5) as

chapters/gnn\_tagger/figs/results/main/ttbar/ttbar\_roc\_btag.pdf

**Figure 5.5:** The  $c$ -jet (left) and light-jet (right) rejections as a function of the  $b$ -jet tagging efficiency for jets in the  $t\bar{t}$  sample with  $20 < p_T < 250$  GeV. The ratio with respect to the performance of the DL1r algorithm is shown in the bottom panels. A value of  $f_c = 0.018$  is used in the calculation of  $D_b$  for DL1r and  $f_c = 0.05$  is used for GN1 and GN1 Lep. Binomial error bands are denoted by the shaded regions. At  $b$ -jet tagging efficiencies less than  $\sim 75\%$ , the light-jet rejection becomes so large that the effect of the low number of jets is visible. The lower  $x$ -axis range is chosen to display the  $b$ -jet tagging efficiencies usually probed in these regions of phase space.

chapters/gnn\_tagger/figs/results/main/zprime/zprime\_roc\_btag.pdf

**Figure 5.6:** The  $c$ -jet (left) and light-jet (right) rejections as a function of the  $b$ -jet tagging efficiency for jets in the  $Z'$  sample with  $250 < p_T < 5000$  GeV. The ratio with respect to the performance of the DL1r algorithm is shown in the bottom panels. A value of  $f_c = 0.018$  is used in the calculation of  $D_b$  for DL1r and  $f_c = 0.05$  is used for GN1 and GN1 Lep. Binomial error bands are denoted by the shaded regions. At  $b$ -jet tagging efficiencies less than  $\sim 20\%$ , the light-jet rejection becomes so large that the effect of the low number of jets is visible. The lower  $x$ -axis range is chosen to display the  $b$ -jet tagging efficiencies usually probed in these regions of phase space.

chapters/gnn\_tagger/figs/results/main/ttbar/ttbar\_effs\_btag.pdf

**Figure 5.7:** The  $b$ -jet tagging efficiency for jets in the  $t\bar{t}$  sample (left) and jets in the  $Z'$  sample (right) as a function of jet  $p_T$  with a fixed light-jet rejection of 100 in each bin. A value of  $f_c = 0.018$  is used in the calculation of  $D_b$  for DL1r and  $f_c = 0.05$  is used for GN1 and GN1 Lep. Binomial error bands are denoted by the shaded regions.

$$D_c = \log \frac{p_c}{(1 - f_b)p_l + f_b p_b}. \quad (5.6)$$

A value of  $f_b = 0.2$  is used for all models. Similar to section 5.5.1, performance of the different taggers is compared by scanning through a range of  $c$ -jet tagging efficiencies and plotting the corresponding  $b$ - and light-jet rejection rates. As in section 5.5.1, WPs are defined using jets in the  $t\bar{t}$  sample. Standard  $c$ -jet tagging efficiency WPs are significantly lower in comparison with the  $b$ -tagging WPs in order to maintain reasonable  $b$ - and light-jet rejection rates. This is reflected in the range of  $c$ -jet tagging efficiencies used in figs. 5.8 and 5.9. In fig. 5.8, which displays the  $c$ -tagging performance of the models on the jets in the  $t\bar{t}$  sample, GN1 performs significantly better than DL1r. The  $b$ - and light-jet rejection improve most at lower  $c$ -jet tagging efficiencies, with both background rejections increasing by a factor of 2 with respect to DL1r at a  $c$ -jet tagging efficiency of 25%. GN1 Lep outperforms GN1, with the  $b$ -rejection (light-jet rejection) relative improvement increasing from a factor of 2 to 2.1 (2 to 2.3) at the 25%  $c$ -jet WP. fig. 5.9 shows the  $c$ -tagging performance on the jets in the  $Z'$  sample. Both GN1 and GN1 Lep perform similarly, improving the  $b$ -rejection by 60% and the light-jet rejection by a factor of 2 at the 25%  $c$ -jet WP.

### 5.5.3 Ablations

Several ablations, the removal of components in the model to study their impact, are carried out to determine the importance of the auxiliary training objectives of GN1 to the overall performance. The “GN1 No Aux” variant retains the primary jet classification objective, but removes both track classification and vertexing auxiliary objectives (see section 5.4.2) and as such only minimises the jet classification loss. The “GN1 TC” variant includes track classification but not vertexing, while “GN1 Vert” includes vertexing, but not track classification.

For jets in both the  $t\bar{t}$  and  $Z'$  samples, the models without one or both of the auxiliary objectives display significantly reduced  $c$ - and light-jet rejection when compared with the baseline GN1 model, as shown in figs. 5.10 and 5.11. For jets in the  $t\bar{t}$  sample, the performance of GN1 No Aux is similar to DL1r, while GN1 TC and GN1 Vert perform similarly to each other. For jets in the  $Z'$  sample, the GN1 No Aux model

The lower  $x$ -axis range is chosen to display the  $c$ -jet tagging efficiencies usually probed in these regions of phase space.

shows a clear improvement in  $c$ - and light-jet rejection when compared with DL1r at lower  $b$ -jet tagging efficiencies. Similar to jets in the  $t\bar{t}$  sample, GN1 TC and GN1 Vert perform similarly, and bring large gains in background rejection when compared with GN1 No Aux, but the combination of both auxiliary objectives yields the best performance.

It is notable that the GN1 No Aux model matches or exceeds the performance of DL1r without the need for inputs from the low-level algorithms. This indicates that the performance improvements enabled by GN1 appear to be able to compensate for the removal of the low-level algorithm inputs. The GN1 TC and GN1 Vert variants each similarly outperform DL1r, demonstrating that both contribute to the overall high performance of the baseline model.

#### 5.5.4 Inclusion of Low-Level Vertexing Algorithms

GN1 does not include inputs from low-level tagging algorithms, including the vertexing tools SV1 and JetFitter [37]. Since these algorithms are known to improve the performance of DL1r, it was feasible that their inclusion in GN1 may further improve on the performance of the GN1 models. In a dedicated training of GN1 the SV1 and JetFitter tagger outputs were added to the GN1 jet classification network as an input, similar to their use in DL1r. These outputs include information on the reconstructed vertices, including the number of vertices, the vertex mass, displacement, and other properties. In addition, the index of the reconstructed SV1 or JetFitter vertices were included as two track-level inputs to GN1. The jet classification performance of this GN1 model was not significantly different to the baseline model, and in some cases the performance was slightly reduced. A dedicated look at the vertexing performance of GN1 with some comparisons to SV1 and JetFitter is found in section 5.5.5

#### 5.5.5 Vertexing Performance

From the track-pair vertex prediction described in section 5.4.2, tracks can be partitioned into compatible groups representing vertices (see [35]). As such, GN1 is able to be used to perform vertex “finding”, but not vertex “fitting”, i.e. the reconstruction of a vertex’s properties, which currently still requires the use of a dedicated vertex

chapters/gnn\_tagger/figs/results/ablations/ttbar/ttbar\_roc\_btag.pdf

**Figure 5.10:** The  $c$ -jet (left) and light-jet (right) rejections as a function of the  $b$ -jet tagging efficiency for  $t\bar{t}$  jets with  $20 < p_T < 250$  GeV, for the nominal GN1, in addition to configurations where no (GN1 No Aux), only the track classification (GN1 TC) or only the vertexing (GN1 Vert) auxiliary objectives are deployed. The ratio to the performance of the DL1r algorithm is shown in the bottom panels. A value of  $f_c = 0.018$  is used in the calculation of  $D_b$  for DL1r and  $f_c = 0.05$  is used for GN1. Binomial error bands are denoted by the shaded regions. At  $b$ -jet tagging efficiencies less than  $\sim 65\%$ , the light-jet rejection become so large that the effect of the low number of jets are visible. The lower  $x$ -axis range is chosen to display the  $b$ -jet tagging efficiencies usually probed in these regions.

**Figure 5.11:** The  $c$ -jet (left) and light-jet (right) rejections as a function of the  $b$ -jet tagging efficiency for  $Z'$  jets with  $250 < p_T < 5000$  GeV, for the nominal GN1, in addition to configurations where no (GN1 No Aux), only the track classification (GN1 TC) or only the vertexing (GN1 Vert) auxiliary objectives are deployed. The ratio to the performance of the DL1r algorithm is shown in the bottom panels. A value of  $f_c = 0.018$  is used in the calculation of  $D_b$  for DL1r and  $f_c = 0.05$  is used for GN1. Binomial error bands are denoted by the shaded regions. At  $b$ -jet tagging efficiencies less than  $\sim 25\%$ , the light-jet rejection become so large that the effect of the low number of jets are visible. The lower  $x$ -axis range is chosen to display the  $b$ -jet tagging efficiencies usually probed in these regions.

fitter. In order to study the performance of the different vertexing tools inside  $b$ -jets, the truth vertex label of the tracks, discussed in section 5.4.2, are used. To estimate the efficiency with which GN1 manages to find vertices inclusively, vertices from GN1 containing tracks identified as coming from a  $b$ -hadron are merged together and compared to the inclusive truth decay vertices that result from a  $b$ -hadron decay (where if there are multiple distinct truth vertices from a  $b$ -hadron decay they are also merged together). Vertices are compared with the target truth vertex and the number of correctly and incorrectly assigned tracks is computed. Since secondary vertex information is only recovered for reconstructed tracks, an efficiency of 100% here denotes that all possible secondary vertices are recovered given the limited track reconstruction efficiency. A vertex is considered matched if it contains at least 65% of the tracks in the corresponding truth vertex, and has a purity of at least 50%. GN1 manages to achieve an inclusive reconstruction efficiency in  $b$ -jets of  $\sim 80\%$ , demonstrating that it effectively manages to identify the displaced vertices from  $b$ -hadron decays.

## More detail

In order to study the performance of the different vertexing tools inside  $b$ -jets, the truth vertex label of the tracks, discussed in section 5.4.2, is used. The reconstructed vertices from GN1, SV1 and JetFitter are compared to the target truth vertices in order to calculate the efficiencies of the different vertexing tools. Since secondary vertex information is only recovered for reconstructed tracks, an efficiency of 100% here denotes that all possible secondary vertices are recovered given the limited track reconstruction efficiency.

There are several caveats to a comparison of the vertexing tools which are a result of the different approaches they take to vertexing. SV1 and JetFitter are designed to only find secondary vertices in the jet, whereas GN1 is also trained to determine which tracks in the jet belong to the primary vertex (the vertex of the hard scatter  $pp$  interaction). To account for this the GN1 vertex with the largest number of predicted primary tracks is excluded from the vertex finding efficiency calculation. While JetFitter and GN1 aim to resolve each displaced vertex inside the jet, such that secondary vertices from  $b$ -hadron decays are found separately to tertiary vertices from  $b \rightarrow c$  decay chains, SV1 by design attempts to find a single inclusive vertex

per jet. This inclusive vertex groups inclusive  $b$ -hadron decays. These are tracks from the  $b$ -hadron decay itself (FromB) and tracks from  $b \rightarrow c$  decays (FromBC). In order to fairly compare the performance of the different tools, both the exclusive and inclusive vertex finding efficiency is studied. For the exclusive vertex finding case JetFitter and GN1 can be directly compared, while a comparison with SV1 is not possible due to aforementioned design constraints. The inclusive vertex finding performance of all three tools can be compared using the procedure outlined below.

The starting point for the secondary vertex finding efficiency in both the exclusive and inclusive cases is to select truth secondary vertices are those containing only inclusive  $b$ -hadron decays to be considered as initial targets. For exclusive vertex finding, these truth secondary vertices can be used directly as the denominator for the efficiency calculation. Meanwhile for the inclusive efficiency all such truth secondary vertices in the jet are merged into a single inclusive target vertex. Correspondingly, for the inclusive vertex finding case, the vertices found by JetFitter are merged into a single vertex, and the vertices found by GN1 with at least one predicted inclusive  $b$ -hadron decay track are also merged similarly. SV1 does not require any vertex merging.

Next, in both cases for each truth secondary vertex, vertices in the jet found by the different vertexing tools are compared with the target truth vertex. The number of correctly and incorrectly assigned tracks is computed. In order to call a vertex efficient, it is required to contain at least 65% of the tracks in the corresponding truth vertex, and to have a purity of at least 50%. Single track vertices are required to have a purity of 100%. Additionally, for GN1 only, at least one track in the vertex is required to have a predicted heavy flavour origin.

Vertex finding efficiencies for  $b$ -jets in the  $t\bar{t}$  sample are displayed as a function of  $p_T$  separately for the inclusive and exclusive approaches in fig. 5.12. For  $b$ -jets in the  $t\bar{t}$  sample with  $20 < p_T < 250$  GeV, the exclusive vertex finding efficiency of JetFitter and GN1 is relatively flat as a function of  $p_T$ . Of the truth secondary vertices in this  $p_T$  region, JetFitter efficiently finds approximately 40% and GN1 finds approximately 55%. When finding vertices inclusively the vertex finding efficiency is generally higher. An increased dependence on  $p_T$  is also visible for JetFitter and SV1. As the jet  $p_T$  increases from 20 GeV to 100 GeV, the efficiency of JetFitter increases from 55% to 65%. In the same range, the efficiency of SV1 increases from 55% to 75%. GN1 displays less dependence on  $p_T$  than JetFitter and SV1, efficiently

**Figure 5.12:** Vertex finding efficiency as a function of jet  $p_T$  for  $b$ -jets in the  $t\bar{t}$  sample using the exclusive (left) and inclusive (right) vertex finding approaches. Efficient vertex finding requires the recall of at least 65% of the tracks in the truth vertex, and allows no more than 50% of the tacks to be included incorrectly. Binomial error bands are denoted by the shaded regions.

finding upwards of 80% of vertices in  $b$ -jets in this  $p_T$  region. For  $b$ -jets with  $p_T > 100$  GeV, JetFitter finds approximately 65% of vertices, SV1 finds appromimately 75% of vertices, and GN1 finds approximately 80% of vertices.

For  $b$ -jets in the  $Z'$  sample, the vertex finding efficiency drops steeply with increasing  $p_T$  up until  $p_T = 3$  TeV. GN1 outperforms SV1 and JetFitter across the  $p_T$  spectrum. In the first bin, the efficiency of GN1 is 75%, while the efficiencies of SV1 and JetFitter are around 60%. The efficiency of SV1 drops rapidly to almost zero above 3 TeV, while JetFitter and GN1 retain approximately 30% efficiency. fig. 5.13 compares the exclusive vertex finding efficiencies of JetFitter and GN1 for multi-track vertices. JetFitter finds 45-50% of vertices in  $b$ -jets in the  $t\bar{t}$  sample, while GN1 finds 60-65%. For  $b$ -jets in the  $Z'$  sample, JetFitter finds 35% of vertices in the first bin, dropping to 20% of vertices above 2 TeV. GN1 finds 55% of vertices in the first bin, dropping to 30% above 2 TeV.

### 5.5.6 Track Classification Performance

As discussed in section 5.4.2, one of the auxiliary training objectives for GN1 is to predict the truth origin of each track in the jet. Since the equivalent information is

**Figure 5.13:** Inclusive vertex finding efficiency for multitrack truth vertices in  $b$ -jets in the  $t\bar{t}$  sample (left) and jets in the  $Z'$  sample (right) as a function of jet  $p_T$ . Efficient vertex finding requires the recall of at least 65% of the tracks in the truth vertex, and allows no more than 50% of the tracks to be included incorrectly.

not provided by any of the existing flavour tagging tools, as a benchmark a multi-class classification multilayer perceptron (MLP) is trained on the same tracks used for the baseline GN1 training. The model uses the same concatenated track-and-jet inputs as GN1 (see section 5.4.1), but processes only a single track at a time. The model is comprised of five densely connected layers with 200 neurons per layer, though the performance was not found to be strongly sensitive to changes in the network structure. To measure the track classification performance, the area under the curve (AUC) of the receiver operating characteristic (ROC) curve is computed for each origin class using a one versus all classification approach. The AUCs for the different truth origin classes are averaged using both an unweighted and a weighted approach. The unweighted mean treats the performance of each class equally, while the weighted mean uses the fraction of tracks from each origin as a weight. As seen in table 5.4, GN1 outperforms the MLP, both at  $20 < p_T < 250$  GeV for jets in the  $t\bar{t}$  sample, and at  $250 < p_T < 5000$  GeV for jets in the  $Z'$  sample. For tracks in jets in the  $t\bar{t}$  sample, GN1 can reject 65% of fake tracks while retaining more than 99% of good tracks. The GN1 model has two advantages over the MLP which can explain the performance improvement. Firstly, the mixing of information between tracks, enabled by the fully connected graph network architecture as discussed in section 5.4.3, is likely to be beneficial since the origins of different tracks within

a jet are to some extent correlated. Secondly, the jet classification and vertexing objectives can be considered auxiliary to the track classification task, and may bring improved track classification performance with respect to the standalone MLP.

**Table 5.4:** The area under the ROC curves (AUC) for the track classification from GN1, compared to a standard multilayer perceptron (MLP) trained on a per-track basis. The unweighted mean AUC over the origin classes and weighted mean AUC (using as a weight the fraction of tracks from the given origin) is provided. GN1, which uses an architecture that allows track origins to be classified in a conditional manner as discussed in section 5.4.3, outperforms the MLP model for both  $t\bar{t}$  and  $Z'$  jets.

		AUC	
		Mean	Weighted
$t\bar{t}$	MLP	0.87	0.89
	GN1	<b>0.92</b>	<b>0.95</b>
$Z'$	MLP	0.90	0.94
	GN1	<b>0.94</b>	<b>0.96</b>

fig. 5.14 shows the track origin classification ROC curves for the different track origins for jets in both the  $t\bar{t}$  and  $Z'$  samples. In order to improve legibility of the figure, the heavy flavour truth origins have been combined weighted by their relative abundance, as have the Primary and OtherSecondary labels. In jets in both the  $t\bar{t}$  and  $Z'$  samples, the AUC of the different (grouped) origins is above 0.9, representing good classification performance. Fake tracks, followed by pileup tracks, are the easiest to classify in both samples.

## 5.6 Conclusion

A novel jet tagger, GN1, with a graph neural network architecture and trained with auxiliary training targets, is presented and now fully implemented in the ATLAS software. GN1 is shown to improve flavour tagging performance with respect to DL1r, the current default ATLAS flavour tagging algorithm, when compared in simulated collisions. GN1 improves  $c$ - and light-jet rejection for jets in the  $t\bar{t}$  sample with  $20 < p_T < 250$  GeV by factors of  $\sim 2.1$  and  $\sim 1.8$  respectively at a  $b$ -jet tag-

**Figure 5.14:** ROC curves for the different groups of truth origin labels defined in table 5.2 for jets in the  $t\bar{t}$  sample (left) and jets in the  $Z'$  sample (right). The FromB, FromBC and FromC labels have been combined, weighted by their relative abundance, into the Heavy Flavour category, and the Primary and OtherSecondary labels have similarly been combined into a single category. The mean weighted area under the ROC curves (AUC) is similar for both samples.

ging efficiency of 70% when compared with DL1r. For jets in the  $Z'$  sample with  $250 < p_T < 5000$  GeV, GN1 improves the  $c$ -rejection by a factor of  $\sim 2.8$  and light-jet rejection by a factor of  $\sim 6$  for a comparative  $b$ -jet efficiency of 30%. Previous multivariate flavour tagging algorithms relied on inputs from low-level tagging algorithms, whereas GN1 needs no such inputs, making it more flexible. It can be easily fully optimised via a retraining for specific flavour tagging use cases, as demonstrated with  $c$ -tagging and high- $p_T$   $b$ -tagging, without the need for time-consuming retuning of the low-level tagging algorithms. The model is also simpler to maintain and study due to the reduction of constituent components. GN1 demonstrates improved track classification performance when compared with a simple per-track MLP and an efficiency of  $\sim 80\%$  for inclusive vertex finding in  $b$ -jets. The auxiliary track classification and vertex finding objectives are shown to significantly contribute to the performance in the jet classification objective, and are directly responsible for the improvement over DL1r. Further studies need to be undertaken to verify the performance of GN1 on collision data.

## Chapter 6

### VHbb Boosted Analysis

Paper abstract :

The associated production of a Higgs boson with a  $W$  or  $Z$  boson decaying into leptons and where the Higgs boson decays to a  $b\bar{b}$  pair is measured in the high vector-boson transverse momentum regime, above 250 GeV, with the ATLAS detector. The analysed data, corresponding to an integrated luminosity of  $139\text{ fb}^{-1}$ , were collected in proton–proton collisions at the Large Hadron Collider between 2015 and 2018 at a centre-of-mass energy of  $\sqrt{s} = 13\text{ TeV}$ . The measured signal strength, defined as the ratio of the measured signal yield to that predicted by the Standard Model, is  $0.72^{+0.39}_{-0.36}$  corresponding to an observed (expected) significance of 2.1 (2.7) standard deviations. Cross-sections of associated production of a Higgs boson decaying into  $b$  quark pairs with a  $W$  or  $Z$  gauge boson, decaying into leptons, are measured in two exclusive vector boson transverse momentum regions, 250–400 GeV and above 400 GeV, and interpreted as constraints on anomalous couplings in the framework of a Standard Model effective field theory.

Final states containing zero, one and two charged leptons (electrons or muons) are considered. targeting the decays  $Z \rightarrow \nu\nu$ ,  $W \rightarrow \ell\nu$  and  $Z \rightarrow \ell\ell$ . The  $H \rightarrow b\bar{b}$  decay is reconstructed using a jet with transverse momentum  $p_T > 250\text{ GeV}$ , found with the anti- $k_\perp$   $R = 1.0$  jet algorithm, and groomed to remove soft and wide-angle radiation and to mitigate contributions from the underlying event and additional proton-proton collisions. Higgs bosons are identified using  $b$ -tagged  $R = 0.2$  track-jets matched to the groomed large- $R$  calorimeter jets.

## 6.1 Overview

Lifted from old Vhbb preamble chapter:

The Higgs boson, discovered at the LHC in 2012, is predicted by the standard model to decay primarily to two  $b$  quarks, with a branching factor of  $0.582 \pm 0.007$  [62]. Observation of this decay mode was recently reported by ATLAS [29]. Whilst the dominant Higgs production mode at the LHC is gluon-gluon fusion, this mode has an overwhelming QCD multijet background and so sensitivity to the Higgs is low. The  $H \rightarrow b\bar{b}$  observation therefore searched for Higgs bosons produced in association with a vector boson (W or Z). This production mechanism results in leptonic final states from the decay of the vector boson, allowing for leptonic triggering, whilst at the same time significantly reducing the multi-jet background.

A closely related analyses now searches for the  $H \rightarrow b\bar{b}$  decay of the Higgs boson, produced in association with a vector boson, when the vector boson and Higgs are highly boosted. The full Run-2 dataset is used for a total integrated luminosity of  $139 \text{ fb}^{-1}$ . The analysis is split into 0-, 1- and 2-lepton channels depending on the number of selected electrons and muons, to target the  $ZH \rightarrow \nu\nu b\bar{b}$ ,  $WH \rightarrow \ell\nu b\bar{b}$ ,  $ZH \rightarrow \ell\ell b\bar{b}$  processes, respectively, where  $\ell$  is an electron or muon. In all channels, events are required to have exactly two  $b$ -tagged jets, which form the Higgs boson candidate. At least one of the  $b$ -tagged jets is required to have  $p_T$  greater than 45 GeV. Events are further split into 2-jet or 3-jet categories depending on whether additional, untagged jets are present.

In the 0- and 1-lepton channels, the analysis is further split into signal and control regions. To leading order, there are no additional  $b$ -jets in the event other than the two coming from the reconstructed Higgs candidate. For this reason, there is a signal region veto (i.e. events are not accepted into the signal region) for events with additional  $b$ -tagged jets in the event. Events with additional  $b$ -tagged jets are included in the control region, which is highly pure in  $t\bar{t}$  events. The control region is used to constrain the normalisation of the  $t\bar{t}$  background.

## 6.2 Introduction

Lifted from paper:

Since the discovery of the Higgs boson ( $H$ ) [16–18, 63] with a mass of around 125 GeV [64] by the ATLAS and CMS Collaborations [65, 66] in 2012, the analysis of proton–proton ( $pp$ ) collision data at centre-of-mass energies of 7 TeV, 8 TeV and 13 TeV delivered by the Large Hadron Collider (LHC) [28] has led to precise measurements of the main production cross-sections and decay rates of the Higgs boson, as well as measurements of its mass and its spin and parity properties. In particular, the observation of the decay of the Higgs boson into  $b$ -quark pairs provided direct evidence for the Yukawa coupling of the Higgs boson to down-type quarks [29, 67]. Finally, a combination of 13 TeV results searching for the Higgs boson produced in association with a leptonically decaying  $W$  or  $Z$  boson established the observation of this production process [29]. A first cross-section measurement as a function of the vector-boson transverse momentum was also carried out by the ATLAS Collaboration [68].

The previous ATLAS analyses [29, 68] in this channel were mainly sensitive to vector bosons with transverse momentum ( $p_T$ ) in the range of approximately 100–300 GeV. These analyses considered a pair of jets with radius parameter of  $R = 0.4$ , referred to as small-radius (small- $R$ ) jets, to reconstruct the Higgs boson. For higher Higgs boson transverse momenta, the decay products can become close enough that they cannot be reconstructed with two small- $R$  jets. To explore this ‘boosted’ regime, the Higgs boson is reconstructed as a single large- $R$  jet with  $R = 1.0$  [69]. This high- $p_T$  regime is particularly interesting due to its sensitivity to physics beyond the Standard Model [70].

This Letter presents a measurement of cross-sections for the associated production of a high transverse momentum Higgs boson that decays into a  $b\bar{b}$  pair with a leptonically decaying  $W$  or  $Z$  boson. The analysis uses  $pp$  collision data recorded between 2015 and 2018 by the ATLAS detector [21] during Run 2 at the LHC. This dataset corresponds to an integrated luminosity of  $139\text{ fb}^{-1}$ . Events are selected in 0-, 1- and 2-lepton channels, based on the number of reconstructed charged leptons,  $\ell$  (electrons or muons), in the final state to explore the  $ZH \rightarrow \nu\nu b\bar{b}$ ,  $WH \rightarrow \ell\nu b\bar{b}$  and  $ZH \rightarrow \ell\ell b\bar{b}$  signatures, respectively. The Higgs boson is reconstructed as a

single large- $R$  jet and the  $b$ -quarks from its decay as a pair of jets, reconstructed with a  $p_T$ -dependent radius parameter, associated with the large- $R$  jet and identified as containing a  $b$ -hadron.

The analysis using small- $R$  jets and focusing on slightly lower Higgs boson transverse momentum regions was recently updated with the complete Run 2 dataset [71]. The large- $R$  jet analysis significantly overlaps with the small- $R$  jets analysis. The two results can therefore not be straightforwardly combined.

The dominant background processes after the event selection correspond to the production of  $V + \text{jets}$ , where  $V$  refers to either a  $W$  or  $Z$  boson,  $t\bar{t}$ , single-top and dibosons. The signal is extracted from a combined profile likelihood fit to the large- $R$  jet mass, using several signal and control regions. The yield of diboson production  $VZ$  with  $Z \rightarrow b\bar{b}$  is also measured using the same fit and provides a validation of the analysis. The cross-section measurements are performed within the simplified template cross-section (STXS) framework [72, 73]. These measurements are then used to constrain anomalous couplings in a Standard Model effective field theory (SMEFT) [74].

## 6.3 Modelling Work

### 6.3.1 Background

#### Alternative Samples

As mentioned, alternative samples of  $V + \text{jets}$  events was generated using MADGRAPH5\_AMC@NLO+PYTHIA8, and the results are compared with the nominal SHERPA 2.2.1 samples. This allows for a comparison of different parton showering and underlying event models, and derivation of the systematic uncertainties on the nominal choice of models.

Source of Uncertainty	Implementation
Renormalisation scale ( $\mu_R$ )	Internal weights
Factorisation scale ( $\mu_F$ )	Internal weights
PDF set	Internal weights
$\alpha_S$ value	Internal weights
Parton Shower (PS) models	Alternative samples
Underlying Event (UE) models	Alternative samples
Resummation scale (QSF)	Parameterisation
CKKW merging scale	Parameterisation

**Table 6.1:** Different sources of uncertainty (i.e. variations in the model) considered for V+jets background, and the corresponding implementation. For each uncertainty, acceptance and shape uncertainties are derived.

## Internal Weight Variations

Nominal signal samples generated with SHERPA 2.2.1 include systematic variations of certain modelling parameters which are stored as alternative event weights. The samples contain event weight variations which correspond to variations of renormalisation scale  $\mu_R$ , and factorisation scale  $\mu_F$ , of 0.5 and 2 times the nominal value. Additionally stored is event weight variations corresponding to 30 different variations on the PDF and two variations of the strong coupling constant  $\alpha_S$ . Variations of  $\alpha_S$  were found to have negligible impact on the results of the analysis, and are not discussed further.

## Parameterisation Methods

While the inclusion of internal weight variation in MC event generators has decreased simulation times and increased available statistics, there are in SHERPA 2.2.1 currently some sources of systematic uncertainty that are unable to be stored as internal weight variations due to technical limitations. Two such systematics relate to the choice of CKKW matrix element merging scale, and resummation scale (QSF). The generation of high statistics alternative samples is a time consuming process, as is typically not done for all samples for every new generator release. A method to parameterise the systematic variation using one sample, and to then apply this parameterisation to another sample, has been developed by the ATLAS

SUSY group [75]. This method was used to derive CKKW and QSF uncertainties for the nominal SHERPA 2.2.1 sample, using a previous (lower statistic) SHERPA 2.1 alternative sample. The resulting uncertainties were studied and found to be negligible in comparison with systemics from other sources.

## Shape Uncertainties

In order to derive shape uncertainties (which as the name suggests affect shapes but not overall normalisations of distributions), the following procedure is carried out. Normalised distributions of the reconstructed Higgs candidate mass  $m_J$  are compared for the nominal sample and variations. For each variation, the ratio of the variation to nominal is calculated, and an analytic function is fit to those sources of variation which have a ratio deviating from unity. If different analysis regions or channels show the same pattern of variation, a common uncertainty is assigned. An example of a significant source of uncertainty, arising from choice of factorisation scale  $\mu_R$  is shown in fig. 6.1. An exponential function has been fitted to the ratio of the normalised distributions. Two different analysis regions (medium and high  $p_{T^V}$  bins) are shown. The difference of the shape of the variation means that two separate uncertainties have to be added in the fit, and applied individually in each  $p_{T^V}$  region.

## Acceptance Uncertainties

Several different types of acceptance uncertainties have been calculated. These are implemented as nuisance parameters in the fit and for the most part account for the migration of events between different analysis regions. The list acceptance uncertainties relevant to the V+jets processes are given summarised below.

- **Overall normalisation:** only relevant where normalisation cannot be left floating (i.e. determined in the fit).
- **SR-to-CR relative acceptance:** the uncertainty on the normalisation of the signal region due to events migrating between the signal and control regions.

**Figure 6.1:** Normalised distributions of leading fat jet mass  $m_J$  for medium (6.1a) and high (6.1b)  $p_{T^V}$  analysis regions for W+heavy-flavour-jets in the 0 lepton channel. Merged in heavy flavours, high and low purity signal regions. The renormalisation scale  $\mu_R$  has been varied by a factor of 2 (“1up”) and 0.5 (“1down”). An exponential function has been fit to the ratio.

- **HP-to-LP relative acceptance:** the uncertainty on the normalisation of the high-purity (HP) signal region due to events migrating between the high- and low-purity signal regions.
- **Medium-to-high  $p_{T^V}$  relative acceptance:** describes any ‘shape’ effect in  $p_{T^V}$  distribution, given that the analysis only uses two  $p_{T^V}$  bins (medium and high).
- **Flavour relative acceptance:** for each flavour  $Vxx$ , where  $xx \in \{bc, bl, cc\}$  the ratio of  $Vxx/Vbb$  events is calculated. This corresponds to the uncertainty of  $Vbb$  events due to the miss-tagging of other flavours  $Vxx$ .

The uncertainties on different systematics are summed in quadrature to give a total uncertainty on each region. A summary of the different acceptance uncertainties that were derived in this way and subsequently applied in the fit are given in table 6.2. An effort has been made, wherever possible, to harmonise similar uncertainties across different analysis regions and channels.

### 6.3.2 Vector Boson + Jets Modelling

The background processes involving  $W$  or  $Z$  boson decays into leptons (including those in which the  $W$  boson arises from a top-quark decay) are collectively referred to as electroweak (EW), or V+jets, backgrounds.  $W$ +jets events are most relevant to the 1-lepton channel via the leptonic decay of  $W \rightarrow \ell \nu$ . In the event of  $W \rightarrow \tau \nu$ , and subsequent decay of the  $\tau$ , or the lack of the successful reconstruction of the  $e$  or  $\mu$ ,  $W$ +jets can also contribute to the 0-lepton channel. Meanwhile,  $Z$ +jets contributes primarily to the 0- and 2-lepton channels via the processes  $Z \rightarrow \nu \nu$  and  $Z \rightarrow \ell \ell$  respectively.

Modelling is used to predict the outcomes of the analysis and to assess the impact of sources of different systematic uncertainty. Signal and background modelling has primarily consisted of using Monte Carlo (MC) generators to produce simulated events. The uncertainties on the simulated output must be well understood to perform a successful analysis. To achieve this, a set of “nominal” samples are first defined as a reference to which different variations can be compared. The nominal samples are chosen as the best possible representation of the underlying physical process. “Alternative” samples are used to understand the systematic uncertainties on the nominal samples. To generate an alternative sample, some aspect of the model is varied, and the simulation is re-run. A comparison back to the nominal sample gives a handle on the systematic uncertainty associated with the model parameter which was changed. Detailed information can be found in [76]. In order to access uncertainties associated with the use of MC generators, variations of the data are produced using alternative generators or variation of nominal generator parameters. The variation of nominal generator parameters can in certain cases be implemented using internal weight variations stored alongside the nominal events, and in other cases a new independent sample must be generated. The nominal generator used for V+jets events is SHERPA 2.2.1, while MADGRAPH5\_AMC@NLO+PYTHIA8 (which uses different parton showering models) is used as an alternative generator. As production of large MC samples is computationally expensive, a feature of state of the art simulation packages is to store some sources of variation as internal event weights, which can be generated alongside the nominal samples, saving computation time. Several sources of uncertainty, summarised in table 6.1, have been assessed.

V+jets Acceptance Uncertainties				
Boson	W		Z	
Channel	0L	1L	0L	2L
Vbb Norm.	30%	-	-	-
SR/CR	90% <sup>†</sup>	40% <sup>†</sup>	40%	-
HP/LP	18%		18%	-
High/Medium $p_T^V$	30%	10%*	10%	
Channel Extrap.	20%	-	16%	-
Vbc/Vbb	30%			
Vbl/Vbb	30%			
Vcc/Vbb	20%			
Vcl Norm.	30%			
Vl Norm.	30%			

**Table 6.2:** V+jets acceptance uncertainties.  $W$ +jets SR and CR uncertainties marked with a superscript <sup>†</sup> are correlated. The 1L  $W$ +jets H/M uncertainty marked by \* is applied as independent and uncorrelated NPs in both HP and LP signal regions. The 0L  $W$ +jets Wbb Norm uncertainty is only applied when a floating normalisation for Wbb cannot be obtained from the 1L channel. A 30% uncertainty for Zbb norm is applied in the 1L channel when a floating normalisation for Zbb cannot be obtained from the 0L or 2L channels.

### 6.3.3 Diboson Modelling

## 6.4 Fit Studies

### 6.4.1 Fit Model

A global profile likelihood fit is used to extract the signal strength  $\mu$  and its significance from the data. This statistical setup treats each bin as a Poisson counting experiment. The combined likelihood over  $N$  bins, without considering sources of systematic uncertainty, is given by

$$\mathcal{L}(\mu) = \prod_{i=1}^N \frac{(\mu s_i + b_i)^{n_i}}{n_i!} \exp[-(\mu s_i + b_i)], \quad (6.1)$$

where  $s_i$  ( $b_i$ ) is the expected number of signal (background) events in bin  $i$ , and  $n_i$  is the number of events observed in data in bin  $i$ . The presence of systematic uncertainties which can affect the expected numbers of signal and background events necessitates the addition of nuisance parameters (NPs),  $\theta$ , to the likelihood. Each source of systematic uncertainty for V+jets samples discussed in the previous section was implemented as a NP  $\theta_j$  in the fit. The presence of NPs modifies the likelihood as

$$\mathcal{L}(\mu) \rightarrow \mathcal{L}(\mu, \theta) = \mathcal{L}(\mu) \times \mathcal{L}(\theta), \quad s_i \rightarrow s_i(\theta), \quad b_i \rightarrow b_i(\theta), \quad (6.2)$$

where

$$\mathcal{L}(\theta) = \prod_{\theta_j \in \theta} \frac{\exp[-\theta_j^2/2]}{\sqrt{2\pi}}. \quad (6.3)$$

Post-fit  $m_J$  distributions in the high-purity medium  $p_{T^V}$  regions for the 0- and 2-lepton channels are shown in fig. 6.2. The plots show large falling backgrounds, predominantly made up of  $W$ +jets and  $Z$ +jets events, and a signal distribution corresponding to the Standard Model Higgs boson peaking around  $m_H = 125$  GeV.

**Figure 6.2:** Post-fit distributions for the 0-lepton (6.2a) and 2-lepton (6.2b) channels in the high purity medium  $p_T^V$  region, obtained in the combined conditional  $\mu = 1$  fit to data. The last bin of each plot is an overflow bin.

## 6.5 Conclusion

Work has been carried out as part of the boosted VHbb analysis group to understand, and implement in the global profile likelihood fit, systematic uncertainties on V+jets samples. This background modelling work is an essential part of the success of the analysis. So far the fit has proved stable with the inclusion of the V+jets uncertainties, and detailed studies are now underway to determine the causes behind any observed pulls of the added NPs. Additional work is ongoing to help with the derivation of uncertainties on diboson samples, another important background. The analysis is already advanced, and is now progressing into its final stages. Publication is expected in the new year.

# 1457 List of figures

1458	1.1	The Higgs potential $V(\phi)$ of the complex scalar field $\phi$ , with a choice	
1459		of $\mu^2 < 0$ leading to a continuous degeneracy in the vacuum states. .	15
1460	2.1	The Inner Detector (ID). After run 3, the ID will be replaced by the	
1461		ITk. . . . .	20
1462	2.2	Updated ID, showing the IBL. . . . .	20
1463	2.3	The ECal (orange) and HCal (grey, dark orange) . . . . .	22
1464	2.4	The muon detectors . . . . .	23
1465	3.1	Diagram of a typical $b$ -jet (blue) which has been produced along with	
1466		two light jets (grey). The $b$ -hadron has travelled a significant distance	
1467		from the primary interaction point (pink dot) before its decay. The	
1468		large transverse impact parameter $d_0$ is a characteristic property of	
1469		the trajectories of $b$ -hadron decay products. . . . .	29
1470	3.2	As $b$ -hadron $p_T$ increases, the time of flight of the B increases, so	
1471		tracks will have less room to diverge before reaching detector ele-	
1472		ments. To compound the problem, the collimation of the tracks in-	
1473		creases. The detector may then be unable to resolve individual tracks.	30

1474	3.3	Hit multiplicities on the IBL (3.3a) and the pixel layers (3.3b) as a	
1475		function of the $p_T$ of the reconstructed track. Tracks from the weak	
1476		decay of the $b$ -hadron are shown in red, while fragmentation tracks	
1477		(which are prompt) are in blue. For each of these, standard tracks	
1478		and pseudo-tracks are plotted. Hit multiplicities on the pseudo-tracks	
1479		at high $p_T$ due to the increased flight of the $b$ -hadron. The baseline	
1480		tracks have more hits than the pseudo-tracks, indicating that they	
1481		are being incorrectly assigned additional hits. . . . .	31
1482	3.4	Track reconstruction efficiency from $b$ -hadron decay products for base-	
1483		line ATLAS tracking (black), Bcut+Refit procedures applied (green),	
1484		pseudo-tracking (blue), and for tracking where the ambiguity solver	
1485		has been manually removed (orange). . . . .	31
1486	3.5	The total number of pixel hits on tracks from $b$ -hadron decays as a	
1487		function of the production radius of the decay product. An excess	
1488		of hits is assigned to the standard tracks in comparison to the ideal	
1489		pseudo-tracks. . . . .	31
1490	3.6	Distributions of angular distance $dR$ between $B$ hadrons and their	
1491		weak decays and other fragmentation tracks (fig. 3.6a), and the distri-	
1492		bution of angular distance $dR$ between $B$ hadrons and the calorimeter	
1493		clusters in the hadronic calorimeter (fig. 3.6b). In fig. 3.6a, the tracks	
1494		from the weak decay of the $B$ are significantly more collimated to the	
1495		$B$ than the other fragmentation tracks. . . . .	34
1496	3.7	The distribution of cluster transverse momentum, in fig. 3.7a for both	
1497		clusters that were able (orange) and unable (blue) to be matched to	
1498		a $B$ hadron using MC truth information. The normalisation shows	
1499		that the majority of clusters are not matched to $B$ hadrons, resulting	
1500		in fake ROIs. In fig. 3.7b, the fractional improvement in track fit	
1501		quality ( $\chi^2/n$ ) is shown for all track (blue), tracks with good IBL hits	
1502		(green), and tracks with wrong IBL hits (orange). The distributions	
1503		are overlapping, suggesting that the $\chi^2/n$ improvement is not a good	
1504		discriminator of good and wrong hits. . . . .	35

1505	3.8	Distributions of good (fig. 3.8a) and wrong (fig:refit optimisation re-	
1506		sults sub2) hit assignment rates on the IBL for tracks using baseline	
1507		tracking (black), the original unmodified refit procedure (green), and	
1508		the refit procedure with an optimise set of ROI selection cuts (blue).	
1509		The IBL lies at a radius of 33 mm from the beam pipe. Hence, parti-	
1510		cles produced with a production radius greater than this cannot leave	
1511		good hits on the IBL. . . . .	36
1512	3.9	Profiles, as a function of parent $B$ hadron $p_T$ , of good (fig. 3.9a) and	
1513		wrong (fig. 3.9b) hit assignment rates on the IBL for tracks using	
1514		baseline tracking (black), and various looser values of the outlier cut.	38
1515	5.1	Comparison of the existing flavour tagging scheme (left) and GN1	
1516		(right). The existing approach utilises low-level algorithms (shown in	
1517		blue), the outputs of which are fed into a high-level algorithm (DL1r).	
1518		Instead of being used to guide the design of the manually optimised	
1519		algorithms, additional truth information from the simulation is now	
1520		being used as auxiliary training targets for GN1. The solid lines rep-	
1521		resent reconstructed information, whereas the dashed lines represent	
1522		truth information. . . . .	43
1523	5.2	The inputs to GN1 are the two jet features ( $n_{jf} = 2$ ), and an array of	
1524		$n_{\text{tracks}}$ , where each track is described by 21 track features ( $n_{\text{tf}} = 21$ ).	
1525		The jet features are copied for each of the tracks, and the combined	
1526		jet-track vectors of length 23 form the inputs of GN1. . . . .	50
1527	5.3	The network architecture of GN1. Inputs are fed into a per-track	
1528		initialisation network, which outputs an initial latent representation	
1529		of each track. These representations are then used to populate the	
1530		node features of a fully connected graph network. After the graph	
1531		network, the resulting node representations are used to predict the	
1532		jet flavour, the track origins, and the track-pair vertex compatibility.	50

1533	5.4	Comparison between the DL1r and GN1 $b$ -tagging discriminant $D_b$ for	
1534		jets in the $t\bar{t}$ sample. The 85% WP and the 60% WP are marked by	
1535		the solid (dashed) lines for GN1 (DL1r), representing respectively the	
1536		loosest and tightest WPs used by analyses. A value of $f_c = 0.018$ is	
1537		used in the calculation of $D_b$ for DL1r and $f_c = 0.05$ is used for GN1.	
1538		The distributions of the different jet flavours have been normalised to	
1539		unity area. . . . .	55
1540	5.5	The $c$ -jet (left) and light-jet (right) rejections as a function of the $b$ -jet	
1541		tagging efficiency for jets in the $t\bar{t}$ sample with $20 < p_T < 250$ GeV.	
1542		The ratio with respect to the performance of the DL1r algorithm is	
1543		shown in the bottom panels. A value of $f_c = 0.018$ is used in the	
1544		calculation of $D_b$ for DL1r and $f_c = 0.05$ is used for GN1 and GN1	
1545		Lep. Binomial error bands are denoted by the shaded regions. At $b$ -	
1546		jet tagging efficiencies less than $\sim 75\%$ , the light-jet rejection becomes	
1547		so large that the effect of the low number of jets is visible. The lower	
1548		$x$ -axis range is chosen to display the $b$ -jet tagging efficiencies usually	
1549		probed in these regions of phase space. . . . .	58
1550	5.6	The $c$ -jet (left) and light-jet (right) rejections as a function of the $b$ -jet	
1551		tagging efficiency for jets in the $Z'$ sample with $250 < p_T < 5000$ GeV.	
1552		The ratio with respect to the performance of the DL1r algorithm is	
1553		shown in the bottom panels. A value of $f_c = 0.018$ is used in the	
1554		calculation of $D_b$ for DL1r and $f_c = 0.05$ is used for GN1 and GN1	
1555		Lep. Binomial error bands are denoted by the shaded regions. At $b$ -	
1556		jet tagging efficiencies less than $\sim 20\%$ , the light-jet rejection becomes	
1557		so large that the effect of the low number of jets is visible. The lower	
1558		$x$ -axis range is chosen to display the $b$ -jet tagging efficiencies usually	
1559		probed in these regions of phase space. . . . .	59
1560	5.7	The $b$ -jet tagging efficiency for jets in the $t\bar{t}$ sample (left) and jets	
1561		in the $Z'$ sample (right) as a function of jet $p_T$ with a fixed light-jet	
1562		rejection of 100 in each bin. A value of $f_c = 0.018$ is used in the	
1563		calculation of $D_b$ for DL1r and $f_c = 0.05$ is used for GN1 and GN1	
1564		Lep. Binomial error bands are denoted by the shaded regions. . . . .	59

1565	5.8	The $b$ -jet (left) and light-jet (right) rejections as a function of the	
1566		$c$ -jet tagging efficiency for $t\bar{t}$ jets with $20 < p_T < 250$ GeV. The ratio	
1567		to the performance of the DL1r algorithm is shown in the bottom	
1568		panels. Binomial error bands are denoted by the shaded regions. At	
1569		$c$ -jet tagging efficiencies than $\sim 25\%$ , the light-jet rejection becomes	
1570		so large that the effect of the low number of jets is visible. The lower	
1571		$x$ -axis range is chosen to display the $c$ -jet tagging efficiencies usually	
1572		probed in these regions of phase space. . . . .	61
1573	5.9	The $b$ -jet (left) and light-jet (right) rejections as a function of the $c$ -jet	
1574		tagging efficiency for $Z'$ jets with $250 < p_T < 5000$ GeV. The ratio	
1575		to the performance of the DL1r algorithm is shown in the bottom	
1576		panels. Binomial error bands are denoted by the shaded regions. The	
1577		lower $x$ -axis range is chosen to display the $c$ -jet tagging efficiencies	
1578		usually probed in these regions of phase space. . . . .	61
1579	5.10	The $c$ -jet (left) and light-jet (right) rejections as a function of the	
1580		$b$ -jet tagging efficiency for $t\bar{t}$ jets with $20 < p_T < 250$ GeV, for the	
1581		nominal GN1, in addition to configurations where no (GN1 No Aux),	
1582		only the track classification (GN1 TC) or only the vertexing (GN1	
1583		Vert) auxiliary objectives are deployed. The ratio to the performance	
1584		of the DL1r algorithm is shown in the bottom panels. A value of	
1585		$f_c = 0.018$ is used in the calculation of $D_b$ for DL1r and $f_c = 0.05$	
1586		is used for GN1. Binomial error bands are denoted by the shaded	
1587		regions. At $b$ -jet tagging efficiencies less than $\sim 65\%$ , the light-jet	
1588		rejection become so large that the effect of the low number of jets are	
1589		visible. The lower $x$ -axis range is chosen to display the $b$ -jet tagging	
1590		efficiencies usually probed in these regions. . . . .	63

1591	5.11	The $c$ -jet (left) and light-jet (right) rejections as a function of the	
1592		$b$ -jet tagging efficiency for $Z'$ jets with $250 < p_T < 5000$ GeV, for the	
1593		nominal GN1, in addition to configurations where no (GN1 No Aux),	
1594		only the track classification (GN1 TC) or only the vertexing (GN1	
1595		Vert) auxiliary objectives are deployed. The ratio to the performance	
1596		of the DL1r algorithm is shown in the bottom panels. A value of	
1597		$f_c = 0.018$ is used in the calculation of $D_b$ for DL1r and $f_c = 0.05$	
1598		is used for GN1. Binomial error bands are denoted by the shaded	
1599		regions. At $b$ -jet tagging efficiencies less than $\sim 25\%$ , the light-jet	
1600		rejection become so large that the effect of the low number of jets are	
1601		visible. The lower $x$ -axis range is chosen to display the $b$ -jet tagging	
1602		efficiencies usually probed in these regions. . . . .	64
1603	5.12	Vertex finding efficiency as a function of jet $p_T$ for $b$ -jets in the $t\bar{t}$	
1604		sample using the exclusive (left) and inclusive (right) vertex finding	
1605		approaches. Efficient vertex finding requires the recall of at least 65%	
1606		of the tracks in the truth vertex, and allows no more than 50% of the	
1607		tacks to be included incorrectly. Binomial error bands are denoted	
1608		by the shaded regions. . . . .	67
1609	5.13	Inclusive vertex finding efficiency for multitrack truth vertices in $b$ -jets	
1610		in the $t\bar{t}$ sample (left) and jets in the $Z'$ sample (right) as a function	
1611		of jet $p_T$ . Efficient vertex finding requires the recall of at least 65%	
1612		of the tracks in the truth vertex, and allows no more than 50% of the	
1613		tacks to be included incorrectly. . . . .	68
1614	5.14	ROC curves for the different groups of truth origin labels defined	
1615		in table 5.2 for jets in the $t\bar{t}$ sample (left) and jets in the $Z'$ sample	
1616		(right). The FromB, FromBC and FromC labels have been combined,	
1617		weighted by their relative abundance, into the Heavy Flavour cate-	
1618		gory, and the Primary and OtherSecondary labels have similarly been	
1619		combined into a single category. The mean weighted area under the	
1620		ROC curves (AUC) is similar for both samples. . . . .	70

1621	6.1	Normalised distributions of leading fat jet mass $m_J$ for medium (6.1a)	
1622		and high (6.1b) $p_{T^V}$ analysis regions for W+heavy-flavour-jets in the	
1623		0 lepton channel. Merged in heavy flavours, high and low purity signal	
1624		regions. The renormalisation scale $\mu_R$ has been varied by a factor of	
1625		2 (“1up”) and 0.5 (“1down”). An exponential function has been fit to	
1626		the ratio. . . . .	77
1627	6.2	Post-fit distributions for the 0-lepton (6.2a) and 2-lepton (6.2b) chan-	
1628		nels in the high purity medium $p_{T^V}$ region, obtained in the combined	
1629		conditional $\mu = 1$ fit to data. The last bin of each plot is an overflow	
1630		bin. . . . .	81

# 1631 List of tables

1632	1.1	The half-integer spin fermions of the SM [8]. Three generations of	
1633		particles are present. Also present (unlisted) are the antiparticles,	
1634		which are identical to the particles up to a reversed charge sign. . . .	10
1635	1.2	The integer spin bosons of the SM [8]. The photon, weak bosons and	
1636		gluons are gauge bosons arising from gauge symmetries, and carry	
1637		the four fundamental forces of the SM. . . . .	11
1638	2.1	Characteristics of the trigger levels and offline analysis. . . . .	24
1639	2.2	Quality selections applied to tracks, where $d_0$ is the transverse IP of	
1640		the track, $z_0$ is the longitudinal IP with respect to the PV and $\theta$ is	
1641		the track polar angle. Shared hits are hits used on multiple tracks	
1642		which have not been classified as split by the cluster-splitting neural	
1643		networks [23]. Shared hits on pixel layers are given a weight of 1,	
1644		while shared hits in the SCT are given a weight of 0.5. A hole is a	
1645		missing hit, where one is expected, on a layer between two other hits	
1646		on a track. . . . .	25
1647	5.1	Input features to the GN1 model. Basic jet kinematics, along with in-	
1648		formation about the reconstructed track parameters and constituent	
1649		hits are used. Shared hits, are hits used on multiple tracks which	
1650		have not been classified as split by the cluster-splitting neural net-	
1651		works [23], while split hits are hits used on multiple tracks which	
1652		have been identified as merged. A hole is a missing hit, where one	
1653		is expected, on a layer between two other hits on a track. The track	
1654		leptonID is an additional input to the GN1 Lep model. . . . .	47

1655	5.2	Truth origins which are used to categorise the physics process that	
1656		led to the production of a track. Tracks are matched to charged par-	
1657		ticles using the truth-matching probability [23]. A truth-matching	
1658		probability of less than 0.5 indicates that reconstructed track param-	
1659		eters are likely to be mismeasured and may not correspond to the	
1660		trajectory of a single charged particle. The “OtherSecondary” ori-	
1661		gin includes tracks from photon conversions, $K_S^0$ and $\Lambda^0$ decays, and	
1662		hadronic interactions. . . . .	48
1663	5.3	A summary of GN1’s different classification networks used for the	
1664		different training objectives. The hidden layers column contains a	
1665		list specifying the number of neurons in each layer. . . . .	52
1666	5.4	The area under the ROC curves (AUC) for the track classification	
1667		from GN1, compared to a standard multilayer perceptron (MLP)	
1668		trained on a per-track basis. The unweighted mean AUC over the	
1669		origin classes and weighted mean AUC (using as a weight the frac-	
1670		tion of tracks from the given origin) is provided. GN1, which uses an	
1671		architecture that allows track origins to be classified in a conditional	
1672		manner as discussed in section 5.4.3, outperforms the MLP model for	
1673		both $t\bar{t}$ and $Z'$ jets. . . . .	69
1674	6.1	Different sources of uncertainty (i.e. variations in the model) consid-	
1675		ered for V+jets background, and the corresponding implementation.	
1676		For each uncertainty, acceptance and shape uncertainties are derived.	75
1677	6.2	V+jets acceptance uncertainties. $W$ +jets SR and CR uncertainties	
1678		marked with a superscript $\dagger$ are correlated. The 1L $W$ +jets H/M	
1679		uncertainty marked by $*$ is applied as independent and uncorrelated	
1680		NPs in both HP and LP signal regions. The 0L $W$ +jets Wbb Norm	
1681		uncertainty is only applied when a floating normalisation for Wbb	
1682		cannot be obtained from the 1L channel. A 30% uncertainty for Zbb	
1683		norm is applied in the 1L channel when a floating normalisation for	
1684		Zbb cannot be obtained from the 0L or 2L channels. . . . .	79
